This formula notation is the starting point for most models in R, including ones where explanatory variables are continuous, categorical, or a mixture of both, and when the response variable is a continuous measurement, a count, a proportion, or a category. The types of variables involved determine the type of model used. Typically where explanatory variables are continuous, regression models are used; when they are categorical, analysis of variance (Anova) is used; and when they are both continuous and categorical, analysis of covariance (Ancova) is used. For the response variable, when it is continuous we can

use normal regression, Anova, and Ancova; when it is a proportion (i.e., continuous but within the range of 0–1) or binary (i.e., 0 or 1) we use logistic regression; and when it is a count we use log-linear models. For each of these variations, only minor modifications to the fundamental $y \sim x$ R code are necessary.

Working with radiocarbon dates is a common task for many archaeologists, and although several specialized software tools exist solely for this purpose (e.g., OxCal, BCal), R has established itself as part of the toolkit for innovative analyses of radiocarbon dates. New methods of analyzing sets of radiocarbon dates to model population dynamics have been developed by several R-using archaeologists. Another area where R has become established as the dominant tool is in studies of cultural evolution. In this context, R has been used to model transmission of cultural information, and test hypotheses about population structure and dynamics. Similarly, spatial analyses from hemispheric scales to intra-site scales often use R for modeling archaeological and climate data with a location component. R is also used for zooarchaeology, geoarchaeology, agent-based modeling, and predictive site location modeling in academic and commercial archaeological settings. These more specialized applications are enabled by R packages contributed by researchers and programmers in other disciplines, such as Quaternary science, ecology and evolution, and geography.

A unique characteristic of using R for specialized archaeological applications is that it provides a complete toolkit, not just for the exotic methods, but also for generic activities surrounding the core analysis, such as importing, cleaning, arranging and exploring raw data, testing hypotheses, and visualizing the output with maps and plots. Using R at every step of the research process improves efficiency because it minimizes context switching and manual handling, which may also accidentally introduce errors and confusion.

Future directions

For archaeologists, R has emerged as a universal toolbox with which any kind of data analysis is possible. In addition to the more than 10,000

packages of R functions contributed by users, we can freely write new functions and packages to implement new methods. However, perhaps the most valuable and unique attribute of R is that when writing R code to analyze data, we create an enduring record of all the decisions made during a research project. This record, that is, the R code files, can be archived at a DOI-issuing online repository (e.g., tdar.org, osf.io, figshare.com, zenodo.org). This means we can easily find and reuse it in the future, and we can cite our R code in our publications (Eglen et al. 2017). With our R code freely downloadable from a trustworthy repository, readers of our publications can download and use the R code that generated the results reported in the paper. This is important for the advancement of archaeology because it allows for more complete review of published research, and so a more robust evaluation of its reliability. It also allows for more efficient and rapid transmission of new methods through the research community.

Radiocarbon Calibration and Age Estimation

CHRISTOPHER BRONK RAMSEY

University of Oxford, UK

Radiocarbon dating is one of the most widely used methods to provide age estimates for archaeological material. The method is most often applied to organic material, but in principle it can be used to date any carbonaceous material where the carbon is drawn from a reservoir which contains radiocarbon. Critical to the application of dating in archaeology is the selection of suitable material that relates closely the archaeological events under consideration.

Radiocarbon measurement

Determining the radiocarbon isotopic ratio ($^{14}\text{C}/^{12}\text{C}$) is a multistage process. The first stage is the extraction of chemical components of the sample that are original to the material being dated and free of any contaminants. For archaeological samples where there are a number of possible contaminants, this can be technically complex, and is normally carried out by laboratories that specialize in these types of material. The actual measurement of the radiocarbon isotope ratio can be made using a number of different technologies: originally, methods based on decay rate counting were used, but the majority of measurements are now undertaken using accelerator mass spectrometry (AMS). Corrections are made for mass-dependent fractionation by measurement of the stable isotope $^{13}\text{C}/^{12}\text{C}$ ratio, and for background levels, and the results of such measurements are either reported in terms of fraction modern ($F^{14}\text{C}$) or converted to a nominal conventional radiocarbon age estimate using Libby's original half-life estimate of 5,586 years (Libby, Anderson, and Arnold 1949). The activity of a modern sample is defined as that which a

natural sample would have had in 1950 had there been no fossil fuel effect, and is estimated from measurements on wood from 1850. In practice, all measurements are made relative to standards with precisely known characteristics. The radiocarbon age, A , is expressed in units of years before present (BP), which in this case means before 1950, and is a simple scaled logarithm of the fraction modern, F :

$$A = -8033 \ln(F)$$

This would give the true age of the sample if the amount of radiocarbon in the atmosphere had always been the same as that estimated for the natural atmosphere in 1950 and if the half-life was 5,586 years (Stuiver and Polach 1977). Neither of these is the true, and so the radiocarbon age is best thought of as a convenient logarithmic equivalent to the fraction modern which gives an order of magnitude estimate of true age.

Radiocarbon reservoirs

To use radiocarbon as a precise dating technique requires a detailed record of how radiocarbon has changed in the atmosphere (or other related reservoirs) over time, and to do this requires material that has been dated by other methods. For the Holocene and Late Glacial periods, wood dated by dendrochronology is used, which is ideal because it can be dated to the year and the carbon in wood is directly drawn from the atmosphere through photosynthesis. For earlier periods, a number of different archives are used, including uranium-series dated corals and speleothems, along with marine and terrestrial records. There are estimates for the levels of atmospheric radiocarbon covering the last 50,000 years (Reimer et al. 2013). From the 1950s onward there are also direct atmospheric measurements.

Radiocarbon is mostly generated in the upper atmosphere and becomes incorporated into the global carbon cycle, entering the biosphere through photosynthetic fixing of CO_2 . The mixing rates are such that the radiocarbon in

the atmosphere is fairly constant within each hemisphere, with a slightly lower level (about 0.5%) in the southern hemisphere (Hogg et al. 2013) because of the much larger ocean surface. Terrestrial plants within each hemisphere fix this radiocarbon directly, and so short-lived plants mirror the values found in the atmosphere (albeit with isotopic fractionation), and animals feeding on these plants or higher up the food chain do the same but with some time-averaging, which depends on the tissue concerned. Such effects are usually of the order of a decade or less and are often ignored. Woody plants lay down cellulose over time, and so, for example in trees that have annual tree rings, each ring reflects the prevailing atmospheric radiocarbon level when it grew. When you come to date wood, this can give a very significant “old wood effect,” which needs to be considered in the interpretation.

Through exchange with the atmosphere, radiocarbon is also incorporated into the oceans, but here the mixing rates are much slower and so different bodies of water have very different levels of radiocarbon. The surface oceans on average are about 5 percent (or 400 years) depleted relative to the atmosphere (Reimer et al. 2013), but different regions are affected by ocean upwelling, freshwater runoff, and other effects. In some cases, the offset between the local ocean and marine ocean average (ΔR) can be estimated by looking at paired marine and terrestrial samples (Stuiver and Braziunas 1993), but these offsets are likely to be variable in time and are not available for some regions. These additional uncertainties mean that radiocarbon dating of marine organisms is almost always less precise.

Rivers and other freshwater systems exchange CO_2 with the atmosphere. However, this is mixed with carbon from other sources, including that from detrital carbon in soils, which is depleted in radiocarbon compared to the atmosphere, and dissolved carbonate from the underlying geology (usually virtually free of radiocarbon). This has implications for dating material from fluvial systems and for the radiocarbon dating of speleothems in caves. In practice, it is usually necessary to undertake a local case study to determine such effects.

For humans and other omnivores there is the additional complication that they can, in some cases, source their food from a combination

of terrestrial, marine, and freshwater sources. To account for this, where it might be relevant, requires a detailed dietary analysis as such offsets can be significant (Fernandes, Meadows, and Dreves 2015).

The calibration process

In order to use a radiocarbon measurement for age estimation, we have to calibrate it against known-age material from the relevant reservoir. The first stage in any calibration is therefore the choice of reservoir. Agreed calibration curves are published by the IntCal group (see IntCal Special Issues in the journal *Radiocarbon*.) and cover the three best understood and most widely applicable reservoirs: the atmosphere of the northern hemisphere (currently IntCal13; Reimer et al. 2013), the southern hemisphere atmosphere (SHCal13; Hogg et al. 2013), and the oceans (Marine13; Reimer et al. 2013). These curves give the expected radiocarbon age as a function of true age over the last 50,000 years based on a compilation of different datasets.

Conceptually, the process of calibrating a single sample involves considering each possible year the sample might be from and comparing the measured radiocarbon for the sample to that of the calibration curve estimate for that year. The closer the two values are, the more likely the sample is to be of that age. The mathematical formalism used assumes normally distributed errors, and so strictly is better defined in terms of F^{14}C rather than radiocarbon age. If the radiocarbon calibration curve is defined as a function of time with a standard uncertainty $r_c(t) \pm \sigma_c(t)$ and the sample has a corresponding measurement given by $r_s \pm \sigma_s$ then the likelihood of any date t is proportional to:

$$\frac{\exp\left(-\frac{(r_s - r_c(t))^2}{2(\sigma_s^2 - \sigma_c^2(t))}\right)}{\sqrt{\sigma_s^2 - \sigma_c^2(t)}}$$

The probability density distribution is normalized so that the integrated probability over the full range of the curve is one. Note that the calibration process is independent of the half-life of radiocarbon. It is often useful to express the calibration

Figure 1 Example calibration diagram. The normal distribution on the left shows normal probability distribution associated with radiocarbon determination 3000 ± 30 , expressed in radiocarbon years BP on the y-axis. The calibration curve is shown at $\pm 1\sigma$ as a function of true age on the x-axis. The probability distribution shows the likelihood that the sample is of any particular age. Ranges are given at two different probability levels: for example, there is a 95.4 percent probability that the sample dates to between 1377 and 1126 cal BCE.

as a range and usually this is given as the highest probability density (HPD) range—either at 95 percent or 68 percent to be equivalent to the one and two standard deviation ranges for a normal distribution. The 95 percent range is usually considered to be the most useful, as it is unlikely (<5%) that the date lies outside this. The 68 percent range gives the “most likely” date range. For single date calibrations, it is not considered useful to use the mean and standard deviation, as the distributions following calibration are often multimodal and not normally distributed. Date ranges after calibration are usually expressed in the form of cal BP (where the year 1950 is 0 cal BP), cal AD, cal BC, cal CE, or cal BCE.

Software is available for performing the calibration process, including the widely used CALIB (<http://calib.org>) (Stuiver and Reimer 1993) and OxCal (<http://c14.arch.ox.ac.uk/oxcal.html>) (Bronk Ramsey 2009) packages. Figure 1 shows an example calibration diagram using OxCal. Note that the ranges, as in this case, can be split into several subranges because the probability distribution is multimodal.

Calibration of single samples can take account of offsets from the reservoir level, most commonly in the case of marine samples with a local oceanic ΔR offset (Stuiver and Braziunas 1993). Allowance for mixed reservoirs can also be made when calibrating dates from humans with a mixed terrestrial and marine diet.

Analysis of multiple dates

When there is more than one radiocarbon date to be used for age estimation, it is possible to take into account other information using Bayesian statistical approaches (Buck and Millard 2004; Bronk Ramsey 2009). The types of information that are included in such analyses include samples that share the same age, samples from the same period, and constraints on relative age. In some circumstances, such as lake sediments, we might also have information on the sedimentation process. In the Bayesian approach, this information is included as *prior* probabilities, the radiocarbon measurements themselves are the *likelihood*,

and from these the *posterior* estimate, which includes all information, can be derived. Bayesian chronologies are often site-based, making use of the physical stratigraphy, but they can also be based on regional cultural assemblages or constrained with historical information from written sources.

Regression and Correlation Analysis

OLIVER NAKOINZ

University of Kiel, Germany

Observing and establishing the relationships between variables is one of the most important tools for scientific research in general, not only in archaeology. Regression and correlation analyses are the statistical methods that are used for this task and belong to descriptive statistics (see DESCRIPTIVE STATISTICS).

Regression, correlation, and interpolation are concerned with the relationship between two or more variables. A correlation measures the degree of dependency of two variables. While correlation establishes a degree of relationship, it does not specify the kind of relationship; this is the aim of regression. A regression is the quantitative description of the relationship using a mathematical function. Interpolation estimates the value of a dependent variable based on an independent variable and usually uses regression techniques.

Both regressions and correlations deal with dependencies, themselves one of the main concerns of data analysis and statistics. The general idea is that the relationship between two variables reveals the relationship between the entities of the real world of which the variables are characteristic. If something (A) causes something else (B), the variables a and b should correlate and the regression should be able to provide a mathematical formulation of their dependency. This dependency could suggest that one entity causes the other, that both are caused by a hidden entity, or that they are involved in a complex system of relationships. The problem is to infer the causation from the relationship of the variables as correlation does not imply causation but indicates a possible causal relationship. In particular, correlation does not indicate the direction of causation.

Instead, correlation is a kind of degree of dependency. Usually it is assumed that the relationship between two variables is blurred

by noise (see also ANALYSIS OF VARIANCE AND COVARIANCE). The mathematical formulation of the relationship must consider these effects, which become particularly important when values have to be estimated or predicted.

While August Bravais and Francis Galton provided some ideas, it was Karl Pearson who developed the statistical method of correlation analysis (Nakoinz and Knitter 2016, 87–105; Rodgers and Nicewander 1988; VanPool and Leonard 2011, 221–237). His correlation coefficient, also known as Pearson's product-moment correlation coefficient, is a frequently used measure of the correlation of two variables. This correlation coefficient is the covariance of the two variables divided by the product of their standard deviations. The values range between -1 and 1 , and zero indicates no correlation. The measure is valid for interval scaled numbers. While the Pearson's correlation coefficient (ρ) is defined for whole populations, the sample Pearson's correlation coefficient (r) is defined for samples:

$$r = \frac{\sum_{i=1}^n (x_i - \bar{x})(y_i - \bar{y})}{\sqrt{\sum_{i=1}^n (x_i - \bar{x})^2} \sqrt{\sum_{i=1}^n (y_i - \bar{y})^2}}$$

Both correlation coefficients are used for metric variables. In the case of ordinal variables, Yule's odds ratio (Q) can be used and for nominal variables Pearson's contingency coefficient or Goodman's and Kruskal's λ and τ are worthy approaches.

Francis Galton, who put the method of regression (Fahrmeir et al. 2013; VanPool and Leonard 2011, 178–220) into a statistical context, coined the term “regression.” The idea is that while mathematics traditionally starts with a formula and calculates values, regression works the other way around and reconstructs the formula based on a set of values.

The development of methods of regression originated with the problem of data fitting in astronomy. Adrien-Marie Legendre and Carl Friedrich Gauss developed the least squares method for fitting a function to a set of empirically observed values. Since then, many variants

of regression for different specific purposes have been developed.

The general idea is that the value of the dependent variable (also known as response variable, regressand, explained variable, predicted variable, or output variable, and symbolized with y) depends on the independent variable (also known as explanatory variable, predictor variable, regressor, controlled variable, or input variable, and symbolized with x) and a certain error (ϵ):

$$y = f(x) + \epsilon$$

A regression analysis has at least two steps: the determination of a regression model and the estimation of the regression coefficients. The first step deals with the regression model which is the type of function of the independent variable $f(x)$ in combination with some assumptions. Although it is possible to test the fit of multiple regression models, the decision which to use is usually based on theoretical considerations. The regression model needs to agree with both the theoretical knowledge of the phenomenon and the distribution of data.

The most simple regression model, which will be used as an example, is the simple linear regression model (see **LINEAR MODELS**):

$$f(x) = b_0 + b_1 x,$$

where b_0 is the intercept and b_1 the regression coefficient. In the case of multiple regression, an additional term of the type $b_i x_i$ is added for each covariable. The different covariables allow the expressing of different functions of the same variable. For instance, a polynomial regression model with $x_1 = x^1$, $x_2 = x^2$, and so on can be expressed by a multiple linear regression model. Such transformations allow the researcher a circumvention of the restrictions of a straight line as regression curve and offer a high degree of flexibility. While the linear regression model is the most popular one because of its flexibility, other frequently used regression models are the generalized linear regression model, logit regression model, polynomial regression model, and generalized additive model. Regression models can offer all possible curves.

All regression models are based on certain assumptions. In the case of simple linear models, the assumptions are:

- A linear relationship of the parameters. This assumption is rather trivial for a simple linear regression model with just two parameters but is an important assumption for multiple regression using more than one independent covariable. Many nonlinear models can be transformed to meet this assumption.
- The error of the observations is not correlated.
- The error is homoscedastic, meaning that the error has the same variance for all values of the independent variable.

Multiple regression assumes, in addition, additivity of the errors of the different covariables.

The second step of the regression analysis is the estimation of the regression coefficients (regression parameters). The least squares method is a mathematical technique (see **MATHEMATICS**) which minimizes the sum of the squares of the residuals, the difference between values of the dependent variable derived from the function and from observation. The residuals are a kind of estimated error; thus, by minimizing the residuals, the explanatory power of the regression model is maximized for finding the minimum sum of squares and the partial derivatives of the sum of squares with respect to the regression coefficients is set to zero. An algebraic transformation for simple regression leads to:

$$b_1 = \frac{\sum (y_i - \text{mean}(y)) (x_i - \text{mean}(x))}{\sum (x_i - \text{mean}(x))^2}$$

$$b_0 = \text{mean}(y) - b_1 \text{mean}(x)$$

In the case of normally distributed errors, the maximum likelihood estimation can be applied—this is another frequently used parameter estimation method.

The regression parameters estimated with this method maximize the likelihood of the occurrence of the empirical sample data in a distribution set by certain parameters. Usually, numerical methods such as the Newton–Raphson method are required for calculating the maximum likelihood function.

As a third step of regression analysis, the analysis of residuals can be applied. The general idea is that the regression model offers an explanation of a certain part of the observed variation and that the resulting error in the model is randomly

distributed and cannot be explained. However, the regression analysis results in an estimated error and not in a real value of the error. It is possible that the regression model is not sufficient for explaining all observations. A first indication of additional factors is the presence of outliers. In some cases, specific circumstances can be responsible for the values of the dependent variable and hence produce outliers. These outliers might not be observable with basic statistics such as mean and standard deviation analysis if they are inside the usual range of values. A regression analysis can make the outliers visible because they show that the values of the dependent variable lie inside the range of the whole dataset but not within the range expected for certain values of the independent variable. Certain structures such as autocorrelation of the errors are a second indicator of the importance of additional factors. Autocorrelation refers to a correlation of the differences of values of the independent and differences of values of the dependent variable. In simple words, similar values of the independent variable produce similar values of the dependent variable.

Another common issue in regression analysis is overfitting. The problem of overfitting is best explained by the example of polynomial regression:

$$y = b_0 + b_1x + b_2x^2 + b_3x^3 + \dots$$

The higher the degree of the polynomial, the better the fit of the regression curve. It is possible to produce a perfect fit if the polynomial degree equals the number of observations. If there is an error in the observations, the perfect fit does not make any sense because the regression model would map not only the valid data but also the error. This effect is called overfitting. The optimal degree of the polynomial can be estimated with a multiple subsampling strategy (see *SAMPLING THEORY*). In this method, one part of the observations is used to produce the regression curve and the other part is used to test the regression curve with the least square estimate or the maximum likelihood estimate.

In general, regression and correlation analyses offer a reasonable toolbox for investigating all kinds of relationships of variables. If time is used as the independent variable, the regression results in a model of the development of a certain phenomenon over time. But other variables such

as social indicators can also be investigated. For example, the correlation of the quantity of finds and the size of a burial monument can establish an indicator of social ranks and regression analysis allows the specification of the details of a relationship between the variables. The correlation of size and decoration of ceramic vessels can establish that the size is meaningful.

Fall-off curves are another well-known example of archaeologically useful regression models as they map the frequency of finds over the distance from a source. Mathematical distance decay functions are then used in order to deduce the organization of the exchange system.

Overall, regression models play a central role in landscape and environmental archaeology. Insights into the representativity of archaeological data can be gained by a correlation analysis of vegetation and the density of sites, while the correlation analysis of proxies for social change and environmental change tell something about the interrelationship of humans and the environment. A regression analysis of both sea level and age of sites is a specific type of a transgression curve and enhances the knowledge on archaeological sites and coastlines at different times. Regression analysis is the main tool of predictive modeling (see *PREDICTIVE MODELING*) where correlations between landscape features (e.g., altitude) and the degree of human activity are used to predict unknown sites.

Finally, regression methods are the main technique for predicting unobserved points. Inter- and extrapolation techniques are usually based on regression analysis. Interpolations (Nakoinz and Knitter 2016, 97–104) are carried out for reconstructing surfaces from samples such as coring or point measurements. If the regression does not use an explicit mathematical function, nonparametric methods such as kernel density estimation or kriging are applied.

Sampling Theory

PETER N. PEREGRINE

Lawrence University, USA; Santa Fe Institute, USA

There is a single objective underlying sampling theory: to create a subset of a population in which all cases in the subset have an equal probability of being selected from the population. A sample produced in this way will accurately reflect the range of variation in the population. All probabilistic methods of sampling are designed to achieve this basic objective. Four sampling methods based in probability theory are commonly used in archaeology: simple random sampling, systematic random sampling, stratified sampling, and cluster sampling. These methods all produce samples that match the statistical parameters of the population, and thus meet the requirements for statistical analysis. Several non-probabilistic methods are also commonly used in archaeology, but are not recommended to produce samples intended for analysis beyond basic descriptive statistics (and even these may be misleading).

Probabilistic sampling is based on the assumption that all natural populations have a “normal” distribution of variation from which the proportion of individuals with a given characteristic can be estimated. This assumption is visually demonstrated through the “normal curve” (see, e.g., Thomas 1986, Figure 7.12). A “normal curve” is a form of a histogram, where the range of variation for a given characteristic is shown on the *x*-axis and the number of individuals with that characteristic is shown on the *y*-axis. In a “normal curve” the arithmetic mean (the sum of all individual scores on the given characteristic divided by the number of individuals in the population) is the high point of the curve. The population variance is calculated as the sum of the squared differences between the value of each individual on the given characteristic and the mean, divided by the number of individuals in the population—in essence it is a measure of the average difference between an individual score

and the population mean. In practice the square root of the variance, called the standard deviation, is used to describe the population variance, as it is an arithmetically more useful measure.

Knowing the mean and variance (and standard deviation) of a population with a “normal curve” allows us to estimate the number of individuals in the population with a particular value on a given characteristic. For example, if the population has a mean of 100, a standard deviation of 10, and contains 1000 individuals, we can estimate that there should be about 20 individuals with a value of 110. An accurate sample of 100 individuals from this population should therefore contain 2 individuals with a score of 110. A good sample should contain cases that accurately match the proportion of cases with the same score in the population. Achieving that is the foundation of all probabilistic sampling methods.

Simple random sampling is the purest form of probabilistic sampling. To produce a simple random sample, every case in the population of interest is given a number. Cases for the sample are then selected using a random number generator, so that every case is selected randomly and thus each has an equal probability of selection. A sample produced by simple random sampling will have the same mean and variance as the parent population. Typically, only 10% of cases in the parent population need to be selected in order for a sample to accurately match its mean and variation.

Another method of random sampling is called *systematic random sampling*, and is often easier to perform in practice than simple random sampling. In systematic random sampling every case in the population of interest is assigned a number, just as in simple random sampling. But rather than selecting cases for the sample using a random number generator, in systematic random sampling only two random numbers are used—a random start and a random interval. The case with the random start is the first case selected for the sample, and then every case falling at the random interval following the start case is

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

DOI: 10.1002/9781119188230.saseas0516

selected. For example, given a population of 1000, a researcher might simply use a dice to select a start case, say case number 2, and then a dice for the random interval, say 4. The researcher would select cases 2, 6, 10, 14, 18, 22, and so on for the sample. A sample produced in this manner will, like one produced by simple random sampling, match the mean and variation of the parent population. However, there is a caveat: systematic random sampling should not be used if there is a known or suspected periodicity in the population of interest, as the random start and interval might, by chance, match that periodicity, and thus all cases of a certain kind might be either systematically selected or systematically missed (Orton 2000, 22).

There is a significant problem in doing random sampling in practice, whether simple or systematic—the full range of the parent population is usually not known. Taking a simple example, we might want to do a study of the ceramics from an archaeological site. To create a simple random sample of that population we would first have to identify all the ceramics, which is pragmatically impossible. We know we could not have collected every ceramic unless we excavated the entire site, and even in that case we would have difficulty defining the boundaries of the site itself. And because ceramics are usually fragmentary, we would also have to decide how much of a given ceramic object we need to consider it part of the ceramic population. Because of problems like these, it is impossible to identify a “true” parent population in all but the most unique situations, and we must define them using specific criteria and focusing on a specific point in time and space. Thus, any population used in research is only an approximation of the “true” parent population, and any sample is an approximation of that approximation. This is a problem that no sampling method can overcome and we should remain mindful of it in making generalizations about any population we are studying (Thomas 1986, 439–47).

A second problem with random sampling is that we may be most interested in particular segments of a given parent population, and if these segments are relatively rare in the parent population, they will be equally rare in the sample. To acquire sufficient rare cases to perform

analyses might require a very large, and perhaps quite costly and time-consuming, sample to be taken from the parent population. In addition, if our parent population is spatially dispersed, collecting data on the cases selected through random sampling might be extremely costly and time-consuming, as the sampled cases might be separated by great distances. In both cases a more focused sample, either including more of the cases of interest or identifying cases that are spatially close, might be desired. These can be achieved using stratified or clustered random sampling.

In *stratified random sampling* we select separate random samples from several different groups within the parent population; for example, a random sample of those cases in which we are most interested and a random sample from the rest of the population. Knowing the mean and variance of the individual samples allows us to estimate the mean and variation of the parent population as well. And if our research requires us to compare the cases of interest with the rest of the population, this method of sampling provides a way to identify an adequate number of the rare cases to make those comparisons.

In *cluster sampling* we select simple random samples from defined spatial areas within the parent population. We might, for example, randomly select individual areas within a site and collect data from all cases in those areas. This might make the data collection much less costly and time-consuming than having to go all over the site to collect data from cases selected through simple or systematic random sampling. As with stratified random sampling, we can estimate the mean and variance of the parent population through those of the samples. We can also readily compare various areas within a site or region, if that addresses a question of interest.

Probabilistic samples are technically the only ones that should be used in statistical analyses, but pragmatically this is extremely difficult to achieve in archaeology, primarily because we typically know very little about our parent populations. With this in mind there are also several non-probabilistic sampling methods that are reasonable to use in situations where the parent population is completely unknown or where probabilistic sampling is impossible. These methods do not typically provide samples that match

the mean and variance of the parent population, and thus they cannot be used to make generalizations about the parent population (Kalton 1983, 90).

Opportunistic sampling selects all available individuals with a given characteristic for inclusion in the sample. For example, an archaeologist might analyze all the ceramics available in a local museum collection. *Grab bag sampling* is similar, but the archaeologist would select a group of those ceramics by non-systematic choice; for example, the first 20 ceramic objects s/he found in the museum collection. Grab bag sampling, although it may appear to use a random method, does not, because the probability of selecting a given case changes as items are chosen for the sample. Although often easier than probability sampling, non-probability sampling should only be used when probability sampling is impossible.

Regardless of the sampling technique used, it is important to determine an appropriate sample size. Sample size should balance the cost of collecting data and the accuracy required to evaluate a given hypothesis. By convention, a 10% random sample is considered adequate for most research problems. However, questions where very small differences (or *effect sizes*) between individuals or populations need to be evaluated require a larger sample, and where there are large expected differences, a large sample may actually provide too much accuracy, always finding differences even when they are not actually there (a *Type I error*). Determining sample size is often done

through *power analysis*. There are a number of power calculators on the Internet that provide a quick way to determine the appropriate sample size for a given hypothesis. It is important to note, however, that power analysis is only useful for random samples—another reason why random sampling should always be used whenever possible.

Seriation

MARKO PORČIĆ

University of Belgrade, Serbia

Seriation is a method for relative dating. The purpose of seriation is to arrange archaeological entities into a relative chronological sequence based on their formal properties. Archaeological entities can be analytical units at various scales, such as attributes of artifacts, artifacts, or assemblages of artifacts. Sir Flinders Petrie is credited as the founder of the method, although similar ideas were considered by his contemporaries, mainly John Evans and Pitt Rivers (O'Brien and Lyman 1999). The general principle of seriation is that archaeological entities or units should be rearranged in such a manner as to minimize the dissimilarity between adjacent pairs of entities in the sequence, for example, that the most similar entities are next to each other in the resulting sequence. The underlying logic is that the units that are most similar to each other in their formal properties (e.g., presence or frequency distribution of types in assemblages) are most likely to be close in time (Dunnell 1970). The temporal direction of the sequence (which end of the sequence is the earliest/latest) cannot be determined by seriation alone and must be established independently. O'Brien and Lyman (1999) defined three kinds of seriation:

1. *Phyletic seriation*: This is usually applied to attributes and artifacts, based on qualitative or metric variables. Attributes and objects are seriated based on their similarity (Figure 1a). In most applications, the phyletic seriation is based on the overall subjective judgment of similarity, but it can be made more formal by quantifying the features of analytical units, for example, by recording metric data.
2. *Occurrence seriation*: This is based on presences or absences of elements defining the units. The main principle behind the method is the *concentration principle* (Kendall 1963).

The concentration principle states that archaeological units should be arranged in such a way that the spans of elements (e.g., the span of presence of each attribute, or the span of each type) should be the shortest possible across the seriation sequence. Types can be seriated based on the presences/absences of attributes, and assemblages can be seriated based on the presences/absences of types (Figure 1b).

3. *Frequency seriation*: This was discovered by Alfred Kroeber in the early twentieth century. It is the most sophisticated kind of seriation, as it is performed on frequency data that contain extra information in addition to presence/absence data in occurrence seriations (frequency data can always be reduced to presence/absence data but not vice versa). It is usually applied on assemblages characterized by frequencies of types. The aim of frequency seriation is to order the units in such fashion that the relative frequencies of attributes/types follow a unimodal curve across the seriation sequence, which means that the relative frequency of each attribute/type should display monotonic increase, followed by decrease in relative frequency, after reaching a peak in relative frequency. It is also allowed for attributes/types to have truncated sequences in the sense that the relative frequency of an attribute/type may only increase or decrease across the sequence (Dunnell 1970). If this can be done, the resulting sequence is interpreted as a relative chronological sequence (Figure 1c). Therefore, in addition to the concentration principle, frequency seriation includes the *unimodality principle* or *popularity principle* which is based on empirical generalization that things slowly come into fashion, reach a peak of popularity, and slowly go out of fashion (e.g., different hair styles, clothes designs, architectural styles). It was noted in cases where relative chronology is known independently that frequencies of certain attributes/types of a certain class of material culture indeed change according

Figure 1 Late Neolithic Vinča culture clay figurine eye shapes. (a) Phyletic seriation. (b) Occurrence seriation (hypothetical data). (c) Frequency seriation (hypothetical data).

to or approximating the popularity principle. Three preconditions must be met for seriation to be applicable (Dunnell 1970):

- All units must be of comparable duration. For example, if this precondition is not met, the occurrences or frequencies of attributes/types in different assemblages will also be affected by the duration of assemblage formation rather than by temporal change alone.
- All units must come from the same cultural tradition. This precondition ensures the *heritable continuity* (O'Brien and

Lyman 1999)—the cultural relatedness of units through time.

- All units must come from the same spatial area. This precondition prevents the conflation of temporal and spatial effects on archaeological units—for example, if cultural interaction is dependent on spatial distance, variation in typological composition of assemblages may arise between contemporary assemblages resembling variation due to temporal effects.

There are many techniques of seriation in archaeology. James Ford developed the famous

Figure 2 (a) “Battleship” seriation diagram. (b) Correspondence analysis (CA) plot (based on dataset from panel a).

hand-sorting technique for the frequency seriation (O’Brien and Lyman 1999). The first step was to graphically represent the percentages of types in each assemblage on individual narrow paper strips. The percentage of each type in each assemblage was represented by the width of a horizontal bar. The analyst would rearrange the paper strips until the sequence was such that the relative frequencies of all or at least most of the types behaved in accord with the unimodality principle. The visual patterns resulting from valid seriations constructed by Ford’s method were named “battleship curves,” as they resembled a silhouette of a battleship from a bird’s eye view (Figure 2a).

Brainerd (1951) and Robinson (1951) developed a seriation technique based on a specific quantitative similarity coefficient—the *Brainerd–Robinson (BR) similarity index*. The first step in this technique was to calculate the BR similarity index between all pairs of assemblages. The value of the similarity between assemblages i and j is equal to the sum of differences of percentages between assemblages i and j for all n individual types, subtracted from 200:

$$BR_{ij} = 200 - \sum_{k=1}^n |P_{ik} - P_{jk}|$$

The greater the value of the BR index for a pair of assemblages, the more similar they are. When BR values are calculated for all pairs of assemblages, they are arranged into a quadratic symmetric matrix. In order to obtain the valid seriation sequence, an analyst should rearrange the sequence of rows (and columns) until the matrix takes such form that the values of the BR coefficient are decreasing as one moves away from the main diagonal of the matrix.

With real-world data it is often the case that there is more than one sequence that satisfies the conditions of the seriation (e.g., more than one way to arrange the assemblages to obtain or approximate the unimodal model or to minimize distances between assemblages in a sequence). In theory, one could “try out” every possible sequence and see which, if any, fits the seriation model best. In practice, the number of possible permutations increases rapidly. Even with the aid of the fastest computers, it is not possible to look at each possible permutation, even for a relatively small number of units (Lipo, Madsen, and Dunnell 2015).

For this reason, most seriations in modern archaeology are performed by conceptualizing seriation as a multivariate problem of ordering and then applying an appropriate multivariate technique. Each unit is described by the presence/absence or frequency data in a multidimensional space defined by attributes/types, where each attribute/type represents a dimension, and the particular configuration of presences/absences or frequencies in a particular assemblage defines the position of that assemblage in a multidimensional space. The aim of applying multivariate techniques is to find a single dimension, which accounts for the greatest proportion of variability in the data, and to rank units along that dimension. This dimension is interpreted as time, because it is assumed that temporal effects are the main cause of variability between units (which should be the case if the third precondition of seriation is met). The two most commonly used multivariate techniques are multidimensional scaling (MDS) and correspondence analysis (CA) (see CORRESPONDENCE ANALYSIS). MDS is applied to a matrix of pairwise similarities or distances between objects or assemblages, whereas CA is applied directly to the occurrence of frequency data matrix. The results

of MDS- or CA-based seriations are presented graphically on a 2D scatter-plot (Figure 2b). The first dimension, which accounts for the greatest proportion of variability and is interpreted as time, is presented on the *x* axis. An important criterion for a chronological interpretation of both MDS and CA results is the presence of an arch effect (the tendency of units to form an arch on a 2D scatter-plot). The arch effect is an indicator of unimodality, as it is a mathematical consequence of projecting the multidimensional unimodal gradient in 2D space. In most cases, seriation is performed on samples rather than populations, implying that the resulting solutions are always affected by sampling error; therefore, additional tests are necessary to take this into account (see Lipo et al. 1997).

Cultural transmission theory provided an explanation of why seriation works as a reliable method in archaeology. It was shown by computer simulation that one of the fundamental models in cultural transmission theory, the unbiased transmission (the neutral evolution model), produces approximately unimodal relative frequency patterns (Neiman 1995). It was also shown that space can affect seriation in a predictable manner, which makes it possible to define areas of cultural interaction by using seriation as a criterion for grouping sites—a group of site assemblages conforming to the seriation model can be interpreted as representing one cultural interaction sphere (Lipo et al. 1997).

Significant improvements were made within the cultural transmission theory framework both in the theoretical understanding of the processes that generate seriation patterns and in the development of the method itself. A recently introduced iterative deterministic seriation solution (IDSS) method simultaneously solves several problems (Lipo et al. 2015). It finds the best seriation solution in absolute terms and ensures the goodness of fit by statistically comparing the frequencies of types between assemblages in a sequence, controlling for the sampling error at the same time. It allows for branching seriation solutions—the possibility that units do not fall on a single sequence but may belong to diverging sequences. If once a single regional interaction sphere splits into two spheres (e.g., interaction between two subregions stops), a single seriation sequence with units from both subregions will

at some point branch into two sequences, each made of units from different subregions. The classic seriation method, especially when performed with multivariate techniques, cannot retrieve this pattern. These latest developments demonstrate that the epistemic potential of seriation goes beyond relative dating—it can be used to solve interesting questions of cultural dynamics in both space and time.

Statistics and GIS

MATTHEW H. CONNOLLY
University of Central Arkansas, USA

Statistics contribute strongly to GIS analysis activities including: data exploration, classification, and visualization; spatial analysis; interpolation and modeling; and error calculation and assessment. Exploring, classifying, and visualizing geospatial datasets are essential precursors to GIS analysis relying heavily on descriptive statistics. Inferential statistics enable spatial analysis of point and areal patterns. Remote study areas and/or physical variable collection (e.g., precipitation, elevation, etc.) require statistical surfaces to interpolate (estimate) unmeasured locations. Statistical models explain or predict spatial variable values and patterns. Statistics also inform error calculation and assessment for spatial modeling, interpolation, data digitization, GNSS data collection, and remotely sensed data correction.

Data exploration, classification, and visualization

Aspatial central tendency metrics such as mean, median, and mode, and aspatial dispersion metrics such as variance, standard deviation (SD), and coefficient of variation (CV), are the most common statistics. The CV normalizes the standard deviation by the mean, permitting direct variation comparisons between different datasets and variables. Not conducive to mapping, skew and kurtosis impact GIS analysis because their characteristics affect assumptions and inferential techniques applicable to a dataset. For example, many inferential statistical procedures and linear regression models require normal distributions.

Spatial central tendency metrics include central features, mean centers, and linear directional means (LDMs). Central features have the smallest Euclidean distance to all locations in a dataset,

and may represent point or areal data. Central feature identification plays an important role in locational analysis, facility siting, and service provision (e.g., emergency services, public transportation, etc.). Mean centers represent the average location for a georeferenced point set by separately averaging x and y coordinates. The most common mean center application is the geographical *center of population* calculated every decennial census by the US Census Bureau (McGrew et al. 2014). Weighted mean centers are mean center variants, where x and y coordinates are weighted by an attribute value frequency (e.g., sales volume, rainfall, etc.). LDMs are average directions calculated from the mean angle of a set of linear features. Common LDM applications include analysis of transportation systems, migration patterns, and flight paths, to determine average orientation or directional changes over time. Like aspatial measures, spatial central tendency metrics are strongly influenced by outliers, and require careful interpretation.

Spatial dispersion metrics include standard distance and relative distance. Spatially equivalent to the standard deviation, standard distance measures absolute point dispersion relative to the mean center. Weighted standard distances follow a similar rationale as weighted mean centers, and are appropriate when weighted mean centers best describe average location. Functionally similar to standard distances, standard deviational ellipses additionally consider point pattern orientation, using two axes where x and y coordinate distance variations are considered separately. Spatially analogous to the CV, relative distance divides the standard distance by the radius of a circle with the same area as the study region, and helps researchers make equivalent dispersion comparisons between different size study areas and disparate datasets.

Understanding data classification basics is important because classification schemes and numbers of classes selected influence interpretations of inherent spatial patterns. Equal interval (EI), quantile breaks (QB), natural breaks (NB), and standard deviation breaks (SDB) are the

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

© 2018 John Wiley & Sons, Inc. Published 2018 by John Wiley & Sons, Inc.

DOI: 10.1002/9781119188230.saseas0552

most common classification schemes available in most GIS packages. EI classifications use equal class widths with variable numbers of features in each class. Range EI methods partition differences between maximum and minimum values into desired numbers of classes, occasionally producing misleading results. Non-range EI methods improve pattern interpretation using arbitrary analyst-defined breaks, but may mask internal variation. QBs divide all features equally into predetermined numbers of classes, reducing sampling bias. Quartiles and quintiles are the most common quantile classifications due to the ease of overall pattern interpretation, but individual classes may not be intuitive.

Natural breaks (NB) partition data using *natural* gaps (breaks) in the frequency distribution, to create unequally sized groups of similar and dissimilar values. NB methods highlight extremes in spatial datasets, maximizing and minimizing between-class and within-class variation respectively. “Jenks natural breaks” is the most common technique, and is the default classification in many GIS packages. SDBs use predetermined numbers of standard deviations above and below the mean to separate data into classes, and works best with normally distributed data.

Spatial analysis

Point pattern analysis determines dataset point arrangements to identify spatial process presence or absence, and includes nearest-neighbor analysis (NNA) and quadrat analysis (QA). For point sets, NNA compares the mean nearest-neighbor (Euclidean) distance (NND) to theoretical distributions of random, clustered, and dispersed points. NNA test statistic values greater than, less than, and equal to the random pattern's mean NND suggest clustering, dispersion, and randomness, respectively.

QA uses point frequency within areal tessellations (zones) to determine relative dataset clustering, dispersion, or randomness. Variance mean ratio (VMR) values equal to one, greater than one, and less than one respectively suggest randomness, dispersion, or clustering. The testable QA statistic is a chi-square distribution

generated from the product of the VMR and one less than the total number of quadrats.

Areal pattern analysis determines dataset zonal arrangement, identifying spatial process presence or absence using Moran's I, Local Moran's I, and Getis-Ord G_i^* indices among others. Moran's I provides quantitative global spatial autocorrelation measures using a given attribute's (e.g., precipitation) zone centroid arrangement, and adjacency or Euclidean distance-based spatial weights matrices. Positive Moran's I values suggest that attribute values are more clustered than a random distribution, and negative values suggest more dispersion. Monte Carlo simulation is applied to Moran's I calculations, generating a testable statistic with pseudo p -values (O'Sullivan and Unwin 2010).

Local Moran's I is a local version of global Moran's I, where degrees of spatial autocorrelation are calculated for each study area zone's attribute value (Anselin 1995). Positive Local Moran's I values indicate similar attribute value clustering, and negative values indicate dissimilar values located near each other (dispersion). Mapped with GIS and combined with Moran scatterplots (Anselin 1995), Local Moran's I values and z -scores differentiate between high and low value clusters, and identify influential zones contributing most strongly to corresponding global spatial autocorrelation measures. Getis-Ord G_i^* also identifies clusters of high (hot spots) and low (cold spots) attribute values within a study area (Getis and Ord 1992), using Euclidean distance-based spatial weights matrices.

The “modifiable areal unit problem” (MAUP) and distance criterion selection influences all spatial statistics, because changing distance thresholds yields different resulting pattern interpretations. Multi-distance tools such as Ripley's K help ameliorate this problem. Available in most GIS packages, Ripley's K calculates degrees of clustering or dispersion in a point set at multiple distance intervals. More specifically, Ripley's K $L(d)$ function identifies minimum distances where statistically significant clustering is maximized, as well as distances where point or zone arrangement is unlikely to influence nearby attribute values.

Spatial interpolation and modeling

Statistical surfaces are generated using exact or inexact interpolators. Exact interpolators estimate values at unmeasured locations using measured values, while measured values represent themselves. Conversely, inexact interpolators use measured values to estimate measured and unmeasured values (Chang 2016). Inverse distance weighting (IDW) and Kriging are common exact interpolators, while trend surfaces (TSs), regression, and kernel density estimators (KDEs) are typical inexact interpolators. Inexact interpolators offer benefits such as error calculation and confidence interval estimation.

IDW interpolators use distance decay and a Euclidean distance threshold. Distance decay functions determine nearby point influences within the distance threshold, where higher-order functions increase the influence of points closer to the estimated point, and vice versa. Default IDW implementations use second-order functions, and increasing function order produces smoother surfaces. IDW interpolations are sensitive to distance threshold selection due to the MAUP.

Kriging partitions geospatial datasets into spatial trends, or spatially correlated components based on a cardinal direction, spatial correlations between attribute values at nearby locations, and random error terms, to select optimal spatial weights for unmeasured point interpolation (Chang 2016). Basing optimal weight selection on measured values reduces MAUP influences affecting other interpolators and spatial statistics. Kriged surfaces remove spatial trends (drift), and estimate unknown values using residuals. Kriging is the preferred lidar digital elevation model generation method.

TSs fit polynomial equations to known values, estimating values at all study area locations, and produce highly generalized global spatial patterns that reduce noise introduced by local interpolators. Complex surfaces such as topographic variation (e.g., hills and valleys) require third-order polynomials or higher. Also a global interpolation method, regression estimates values for measured and unmeasured locations using measured values. Regression predicts (estimates) dependent variable values using one or more independent variable values. Additionally,

errors between known and estimated values are calculable for regression models.

KDE interpolators estimate unmeasured values by applying probability density functions (PDFs) to points falling within the kernel's bandwidth (distance threshold). Conceptually, KDEs form a *bump* centered on the estimated point, and all measured value influences within the bandwidth are weighted according to the PDF. Like IDW interpolators, KDE methods are sensitive to the distance threshold selected. This sensitivity is addressed using a fixed or adaptive kernel bandwidth. Ripley's K helps analysts to determine an appropriate fixed bandwidth, while adaptive bandwidths self-adjust kernel bandwidths for each individual point estimated.

Using ordinary least squares (OLS), global linear regression estimates dependent variables from one or more independent variables. OLS models assume normally distributed data, and no spatial structure. Although OLS models are inherently aspatial, they remain insightful spatial analysis tools. For example, searching for evidence of clustering, Connolly and Hagelman (2015) mapped residuals from several multivariate OLS municipal water consumption driver models. OLS residual clustering often suggests spatial process presence, which may be verified using spatial statistics such as Moran's I and Local Moran's I.

Local regression assumes a spatial structure in the dataset, and develops individual models for each point or region. Rather than OLS, local regressions use modified weighted regression, where regression weights are distance thresholds (spatial weights). Geographically weighted regression (GWR) applies PDF kernels with fixed or adaptive bandwidths to each independent variable in the model to estimate the value at the kernel center. Despite its ability to capture spatially varying relationships, GWR's frequent use of varying kernel sizes (i.e., adaptive kernels) can produce multicollinearity problems which inflate overall model fits. Simpler bivariate and multivariate spatial regressions also exist, but are considered semi-local models because uniformity in each independent variable's spatial variation is assumed across the study area (O'Sullivan and Unwin 2010).

Error calculation and assessment

Error assessments are commonly applied to modeling and interpolation results, geometric transformations (e.g., satellite and aerial imagery orthorectification, and paper map georeferencing), and global navigation satellite system (GNSS) data accuracy. Modeling and interpolation results are assessed using validation and cross-validation methods. Validation methods partition data into two groups. The first group is used to develop the model or interpolation, and the second group is used to calculate the difference (error) between the two groups. Cross-validation methods (leave-one-out validation) omit a single observation and use remaining observations to estimate omitted values, and calculate associated errors. This process is repeated for every original dataset observation. Preferred diagnostic statistics for these error assessments are root mean square error (RMSE) and standardized RMSE.

RMSE is also commonly applied to determine errors in satellite and aerial imagery geometric transformations, analogue spatial data digitization (e.g., paper maps), and remotely sensed data co-registration for change detection analysis. These operations all require carefully selected ground control points (GCPs) with precisely known locations. RMSE calculates the error between transformation or correction results, and the GCPs.

GCPs are often collected via roving GNSS receivers, and require their own positional error assessment. GNSS data positional errors result from internal satellite clock, signal transmission and receipt, and satellite geometry problems. Satellite geometry problems are estimated using dilutions of precision (DOPs) measured for horizontal, vertical, and overall position (PDOP) characteristics, with PDOP being most common. PDOP is the ratio of the four most widespread satellites available at a given location, to an idealized areal coverage. PDOP and other positional errors may be partially removed via post-processing techniques, such as differential

correction. Sufficiently large samples can yield a 95% confidence level within two standard deviations of the actual location recorded with the roving GNSS receiver.

Statistics in Archaeology

DAVID L. CARLSON
Texas A&M University, USA

Statistical analysis in archaeology depends on the archaeological record as the main source of observations (see *ARCHAEOLOGICAL RECORD*). The archaeological record consists of objects and features that must be collected, recorded, measured, and organized. The recovery and recording of the archaeological record must be informed by the research questions that will be addressed using its data. Inherent in its definition, statistics may be used to examine groups of empirical observations for the purposes of description, inference, and discovery. Observations on objects include provenience, age, composition, measurements recording size and shape, and measurements recording surface characteristics. Features are bounded spaces that often contain objects. Observations on features include provenance, age, measurements recording size and shape, internal stratigraphy, and counts of different kinds of objects and features. Since archaeological sites are rarely excavated in their entirety, it is important that the objects and features recovered represent the unexcavated parts of the site or of similar sites that have not been excavated. Sampling statistics provide a way of ensuring that the data recovered are representative of the population, and provide estimates of the sample sizes needed to answer the research questions (see *SAMPLING THEORY*).

Statistical analysis of archaeological data generally falls into one of five broad domains: composition (see *COMPOSITIONAL DATA ANALYSIS*), chronology (see *RADIOCARBON CALIBRATION AND AGE ESTIMATION* and *SERIATION*), classification (see *ARCHAEOLOGICAL CLASSIFICATION*), spatial distribution, and quanta (see *QUANTUM ANALYSIS*). All have their origins in the nineteenth century, but the increasing availability of computing equipment after World War II facilitated steady growth in their use. Papers by

Robinson (1951) and Spaulding (1953) addressed chronology (seriation) and classification (association between nominal variables). Since 1958, the journal *Archaeometry* has published object composition studies regularly. The study of assemblage variability may be linked to Binford and Binford's (1966) use of statistical methods to determine whether the variability in tool types within Mousterian sites could be explained by something other than Bordes' suggestion that it represented different cultural groups. In 1968, the publication of *Analytical Archaeology* by David L. Clarke made a strong case for quantitative methods in the field. In the early 1970s, spatial distribution analysis and methods from ecology and geography diffused into archaeology with the publication of Whallon's (1973, 1974) research on space occupation, and the seminal contribution to spatial analysis in archaeology by Hodder and Orton (1976).

Composition studies can be divided into object composition and assemblage composition. Object composition involves careful control over sample size and presentation of results as ratios (parts per million, billion, etc.). Assemblage composition involves less control over sample size and presentation of the results, as counts of different kinds of objects (e.g., the number of each of 66 types of Mousterian tools in a particular stratum). Statistical methods for object composition draw primarily on traditional multivariate statistics (see *COMPOSITIONAL DATA ANALYSIS*). Statistical methods for assemblage composition draw primarily on the ecological literature relating to community composition and species diversity. Chronological studies include methods of seriation that have been developed since Petrie first posed the problem in 1899. Later, Robinson (1951) and Kendall (1963) developed formal criteria and methods for seriating assemblages. Chronometric dating has benefited from the development of Bayesian methods, making it possible to incorporate prior information that has strengthened the kinds of inferences that can be drawn from groups of radiocarbon ages (see *RADIOCARBON CALIBRATION AND AGE ESTIMATION*). Classification studies include methods

to find or create groups of artifacts or features and to explore alternative explanations for those groups. For example, they may represent different chronological periods or differences in the activities performed at the site. Recent developments such as geometric morphometrics allow the analysis of three-dimensional coordinates to describe object shapes and to group them. Analysis of spatial distributions has advanced with the development of geographical information systems (GIS) for managing spatial data, and analytical methods to compare observed data with theoretical spatial distributions (see STATISTICS AND GIS).

Archaeological data measurement is the process of recording observations on objects and features (see MEASUREMENT THEORY). There are four different ways to record a measurement. Nominal or categorical measures assign a label or category. The categories do not have any inherent ordering, but they are mutually exclusive and should be exhaustive. For example, a pot might be painted, incised, or plain. Ordinal measurement assigns a rank value to an object or feature so that one object is larger or smaller, but we cannot say by how much. The third and fourth types of measurement are expressed numerically. Interval measures have an arbitrary zero point (such as temperature scales, calendar dates, and compass directions). Ratio measurements have an absolute zero so that a projectile point that is 5 cm is twice as large as a point that is 2.5 cm. Within ratio measurements, some measurements are discrete, meaning that only integer values are possible. There can be 1, 2, or 3 flakes, but not 2.5 flakes. Other measurements are continuous so that decimal values are possible.

The description and visualization of archaeological data is a first step in verifying the accuracy of the data, identifying outliers, and identifying the data distribution. Descriptive statistics include methods for describing the distribution. Plots provide more information about the distribution of values, including histograms, kernel density plots, cumulative plots, box-and-whiskers plots, and strip plots. One goal of the plots is to see whether the distribution of values resembles a known distribution such as a normal or log-normal distribution for continuous numeric values, or a Poisson distribution for count values. Another goal is to identify observations that seem

anomalous. Anomalous values or outliers may be present in the data as a result of coding or transcription errors, or they may also represent valid observations. In some cases, it would make sense to exclude outliers. Generally, it is preferable to use robust statistics that are not as greatly affected by outliers. Missing values should also be identified at this stage. Handling missing values can involve removing observations or variables with missing values, or imputing values using one of a number of approaches designed to avoid biasing the sample mean and standard deviation.

Descriptive statistics also involve the comparison of two or more variables to determine whether they are correlated or associated with one another. For numeric or ordinal variables, correlation coefficients summarize a tendency for one variable to increase or decrease when another variable increases or decreases (see REGRESSION AND CORRELATION ANALYSIS). For nominal variables, measures of association summarize a tendency for categories of one variable to be associated with categories of another variable (see CHI-SQUARE ANALYSIS).

Inferential statistics involve inferences about populations from samples. Since the data consist of only some of the objects, features, and patterns of association produced in the past, inferential statistics are necessary to draw conclusions that extend beyond the data at hand. If there are two samples it may be important to know whether they derive from the same population. If two variables seem to be related to one another, it may be important to know whether this relationship characterizes the population or is just an artifact of this particular sample. Answering these questions involves two different but related procedures: confidence intervals and hypothesis testing.

Both approaches assume that the observations are independent of one another. This becomes important in archaeology where objects are often fragmented. Fragments of the same object are not independent of one another: an important assumption of inferential statistics. As a result, archaeologists have developed various indices to estimate the number of whole objects represented by a collection of fragments (see LITHICS DATA QUANTIFICATION and POTTERY DATA QUANTIFICATION).

Inferential statistics also play a role in evaluating statistical models. Statistical models generally show the relationships between a response (dependent) variable and a group of explanatory (independent) variables. Analysis of variance (see ANALYSIS OF VARIANCE AND COVARIANCE) is used, primarily, in experimental contexts to determine whether various treatments (explanatory variables) result in difference outcomes (measured with a nominal response variable). When the response variable is numeric, regression analysis (see REGRESSION AND CORRELATION ANALYSIS) summarizes the degree to which variation in the response variable can be predicted by variation in the explanatory variables. Regression analyses include several related methods including multiple linear regression, nonlinear regression, robust regression, logistic regression, and Poisson regression (see LINEAR MODELS). In logistic regression, the response variable is a dichotomy, while in Poisson regression the response variable is a count.

Statistical learning (Hastie, Tibshirani, and Friedman 2009) and exploratory data analysis (Tukey 1977) are umbrella terms for collections of methods that emphasize identifying interesting patterning in the data and using data to construct predictive models. Statistical learning includes traditional multivariate statistical methods (see MULTIVARIATE ANALYSIS) as well as more recently developed approaches. Broadly there are two approaches: supervised and unsupervised (see SUPERVISED PATTERN RECOGNITION). In the supervised approach, we know what the response variable is. However, we want a way of characterizing it using a set of variables. For example, we have obsidian samples from known sources and we want to construct a way of identifying the source for samples from archaeological sites. Unsupervised approaches are more difficult since we have only explanatory variables, and the challenge is to infer the response variable. For example, we have pottery from many sites that we suspect was produced in a few locations and we would like to identify those compositional groups.

A basic problem in multivariate statistics is that it is difficult to visualize relationships between many variables or clusters of observations in multidimensional space. Plots of objects and features using two dimensions or three dimensions

(variables) are straightforward. When there are more than three variables, it is necessary to find a two- or three-dimensional view of the data that captures as much information as possible. For example, in a sample of projectile points, length, width, and thickness are usually correlated with one another since large points tend to be longer, wider and thicker. We could summarize size as a single variable and then construct additional variables that capture aspects of point shape. This is an unsupervised problem since all of the variables are explanatory. The created variables are called latent variables, because they are not directly observable. They are inferred from the correlations between the variables.

Principal components analysis (PCA) is the standard way to accomplish this (see PRINCIPAL COMPONENT ANALYSIS). PCA creates the same number of variables (called principal components) as the original data contain. The first variable contains the greatest amount of covariance between the variables, and the second variable contains the next greatest amount of correlation with the constraint that the correlation between them is zero, and so on. Often the first two or three principal components represent much of the variation in the larger set of original variables. The loadings for each principal component provide an indication of what variables are important on that component, and the scores provide an indication of which objects are similar on that component. The loadings and scores can be plotted separately or overlain on a biplot to examine the patterns in the data. A similar procedure, factor analysis, also extracts latent variables (called factors), but focuses on factors that are interpretable rather than just descriptive (see FACTOR ANALYSIS).

When the data consist of a collection of assemblages (see ASSEMBLAGE), the variables are counts representing the number of artifacts of different types, and correspondence analysis (CA) generally gives better results (see CORRESPONDENCE ANALYSIS). In a cross-tabulation of artifact types by locations, there will often be interactions between combinations of artifacts and locations that are difficult to recognize just by examining the table. One reason is because the artifacts and locations are presented in an arbitrary order, and another is that the sample sizes (i.e., the total number of artifacts in each assemblage) can vary

substantially. CA creates latent variables (called dimensions) for the rows and the columns. Plots of the dimensions can be examined separately or overlain in a biplot, as with PCA. The values on the first dimension can be used to reorder the rows and columns in the original table, and these orderings often provide a good seriation if there are temporal differences between the assemblages.

Another way of reducing the dimensions in a dataset is to compute a measure of distance (see *DISTANCE AND DATA TRANSFORMATION*) between all pairs of rows and to use multidimensional scaling (MDS) to create a reduced set of dimensions based on these distances. There are metric and non-metric versions of the procedure. It is often the case that PCA, CA, and MDS produce very similar configurations, but given the speed of modern computing equipment, it is useful to try all three.

The combination of objects or features into groups based on their similarity is another unsupervised approach. For example, a collection of artifacts might represent multiple stylistic or functional types, but we do not know what they are. In this case we are trying to identify clusters of objects in multidimensional space. Cluster analysis includes two broad approaches: partitioning methods and hierarchical methods (see *CLUSTER ANALYSIS*). Partitioning methods divide the objects into a fixed number of groups. They include K-means, K-medoids, and methods based on density or assumed underlying distributions. K-means divide the data into K groups where K is specified in advance. K-means can be very fast, but it is useful to run the procedure multiple times using different numbers of groups and different starting configurations. Density-based approaches look for areas of high density in multidimensional space to form clusters. Distribution-based methods require the specification of the distribution model (usually multivariate normal), which may not always be appropriate.

Hierarchical methods define cluster memberships for all possible group sizes from 1 (everything is in one group) to N , the number of observations. The results are depicted in a dendrogram showing the progressive reduction (or increase) in the number of groups as the analysis proceeds. Agglomerative methods work

from N to 1, while divisive methods work from 1 to N . Agglomerative clustering requires making four decisions. First, will the variables be equally weighted (e.g., computing standard scores) or not? Second, how will distance be measured? There are multiple distance measures and they can affect the results. Third, how will the distance from an object to a group of objects be measured (sometimes called the clustering method)? Again there are a number of choices. Trying multiple clustering methods is usually advisable. Finally, how many clusters are useful to work with? Divisive clustering is very hard to implement when there are many numeric variables and many observations, so simplifications are necessary. Divisive clustering with presence/absence variables is simpler. An example is the construction of phylogenetic trees.

Hierarchical methods do not require specifying the number of clusters in advance, since membership for all possible cluster sizes is depicted in the dendrogram. However, that just postpones the decision of how many clusters to use. The number of clusters present in the data is not a simple question. There are multiple methods of suggesting the best number of clusters and they often disagree. An equally difficult question is: how “real” are the clusters? To what degree have we just divided random data into homogeneous groups? It is probably more accurate to say that cluster analysis “makes” clusters than to say it “discovers” them. Generally we are creating groups for some purpose such as comparing the groups with external criteria. For example, do the groups show a tendency to be concentrated in certain stratigraphic levels, or certain areas of the site? Are some groups associated with particular features? Do the groups differ in use wear indicators?

Supervised analyses have the advantage that there is a response variable. The goal is to use the explanatory variables to predict the response variable for those cases when it is unknown. Compositional analysis involves samples of objects (stone, ceramics, metal) from known sources (geological or manufacturing) and variables describing their composition (see *COMPOSITIONAL DATA ANALYSIS*). The sources are used to construct predictive equations that can be used to predict the source when it is unknown in order to study ancient trade networks. The

most commonly used method in archaeology is linear discriminant analysis (LDA). Whereas PCA tries to summarize the correlations between groups of variables, LDA tries to construct latent variables that provide the best separation between the sources. The equations generate posterior probabilities that can be used to identify which source an unknown specimen matches most closely. To be reasonably confident that the object belongs to a known source, typicality probabilities are used to see whether the object is a good fit with that compositional group. Other supervised methods that archaeologists are beginning to explore include classification and regression trees, random forests, and support vector machines.

As the variety of statistical methods that can help to answer archaeological questions has increased, the availability of software to implement those procedures has also increased. Each method comes with assumptions and limitations. Methods that test specific hypotheses are still important, but newer methods provide richer ways of interacting with the data to stimulate development of new ideas about how to use the archaeological record to learn about the past.

Supervised Pattern Recognition

IVÁN E. VILLALÓN TURRUBIATES

Instituto Tecnológico y de Estudios Superiores de Occidente (ITESO), Mexico

The term “pattern” refers to an example or model that can be copied. Moreover, it can be interpreted as an imitation of a model as well. Patterns can describe different types of objects that are contained within the physical and abstract worlds by means of their interrelation of data, events, concepts, and context. Therefore, they can be perceived even with a certain level of distortion, ambiguous or incomplete information, or the presence and affectation of noise. As an example, if the letter “P” is distorted, it could be a “P” or an “R,” or even a totally different letter. However, if the letter appears in the word “OARK,” then it has a higher possibility to be the letter “P,” but if it appears in the word “OOAD,” then it is more likely to be the letter “R;” this means that the main context used by the word in the experiment defines the correct letter even with its distortion, which explains the crucial importance of the context in a pattern recognition process (Shih 2010).

The pattern recognition process can be described with two main tasks. One of them is the development of a decision rule that will be based on human knowledge; this is known as the learning process. The rule that has been previously defined for the decision-making process and which will be applied to an unknown pattern is defined as the classification process. The learning process is concerned with the study of recognition mechanisms of patterns by human and other living organisms. The classification process deals with the development of the theory and technique needed for an automatic recognition task. The application of the pattern recognition theory can be grouped as:

- Human–machine interaction and communication: including automatic speech

recognition, optical character recognition (OCR) systems, knowledge extraction from natural language, speech understanding techniques, and image and video processing including artificial vision.

- Biomedical applications: including electrocardiogram (ECG) analysis, electroencephalograms (EEG) analysis, electromyography (EMG) analysis, X-ray analysis, image processing techniques, and audio and signal processing methodologies.
- Physics: including high-energy physics, astronomy, and quantum mechanics.
- Criminology studies: including analysis of fingerprints, handwriting, speech, sound, and photography as evidence.
- Natural resources management: including the main study of agriculture, hydrology, forestry, geology, environment, cloud formation, urban assessment, aerosols, and particles.
- Military applications: All the previous groups are included, adding detection of nuclear hazard, missile guidance and detection, radar and sonar analysis, light detection and ranging (LiDAR) analysis, target identification, and traceability, among others.
- Industrial applications: including computer-aided design and manufacturing, computer simulation in testing and assembly of products, automatic control for quality measurements, and ergonomics.
- Archaeology and anthropology studies: including image processing, radar and sonar analysis, resource management, urban dynamics, and knowledge extraction from remote sensing imagery.

As a definition, pattern recognition is the scientific discipline that focuses on the classification of data, objects, or, in general terms, patterns into categories or classes. To achieve this goal, the methodology is focused on the extraction of information from data observation, learning to recognize the different patterns contained within the data (learning process), and making a decision based on the category of the patterns

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

© 2018 John Wiley & Sons, Inc. Published 2018 by John Wiley & Sons, Inc.

DOI: 10.1002/9781119188230.saseas0562

(classification process). This involves capabilities of unsupervised learning, supervised learning, and adopting minimum risk strategies.

A basic process for pattern recognition is statistically based and focuses on the statistical properties of the patterns (i.e., probability densities). The pattern is represented in a feature space, where the features are an object's characteristics usually expressed with numeric data. The classes or categories are groups of patterns having similar values in its features and, according to a given metric, each class has its own model that is its own mathematical description.

The main goal of the pattern recognition process is to hypothesize the model that describes each population class, to process the data to eliminate noise (values that are not providing useful information for the classification process), to choose the model that better corresponds, and to assign it to the class described by that model.

The unsupervised classification technique can be used to partition a large set of data into groups, called clusters, so that the data points in a group are similar to each other, while those in distinct groups are not similar to those in the other groups. This process is usually selected when the datasets are not originally grouped and the quantity of groups within the data is unknown; however, the datasets can be partitioned into distinct groups based on the similarities or distances among the data points.

The supervised classification technique can be used when the classification is based on a given number of groups and the objective is to assign any new data point to one of these groups. For this process, the number of groups is well known and some data from each group are also known and used to characterize each particular group; therefore, once the new unclassified data points are analyzed, the known information allows the definition of a classification rule to assign those points to a particular group.

Classification process

The main process of classification used by pattern recognition methodologies consists of two stages.

The first stage is the recognition of an object's categories. As an example, considering the context of remote sensing images of the land surface, these categories could include woodlands, water bodies, grassland, and other land cover types, depending on the geographical scale and nature of the study. The second stage in the classification process is the labeling of the entities to be classified; for the considered example, these labels are numerical so that a pixel that is recognized as belonging to the class "water" may be given the label "1," "woodland" may be labeled "2," and so on. Therefore, the process of image classification requires performing the following steps:

- To determine a priori the number of categories in which the image will be described. This is the previously described learning process.
- To assign the numerical labels to the pixel on the basis of their properties using a decision rule. This is the previously described classification process.

Moreover, a set of grayscale values for a single pixel measured in a number of spectral bands contained within the remote sensing image is known as the pattern, and those spectral bands that define the pattern are called features. Therefore, a pattern is the set of measurements on the chosen features for the individuals that are to be classified. The classification process is considered as a pattern recognition methodology for this example: that is, the identification of the pattern associated with each pixel position within the image in terms of the characteristics of the objects or materials that are present at the corresponding point.

Supervised pattern recognition

Supervised classification methods are based on external knowledge of the area within the sample to be studied. Unlike the unsupervised methods, the supervised methodologies require some input from the user (or a priori information) before the chosen algorithm can be applied. This input may be derived from different methodologies; as an example considering remote sensing images,

the a priori information could be provided by fieldwork, air photo analysis, reports, or from the study of known maps for the area of interest. The supervised methods are implemented using two main paradigms: statistical algorithms and neural algorithms. The statistical approach uses parameters that are derived from sampled data in the form of training classes—for example, minimum and maximum values of the features, or the mean values of the individual clusters, or the mean and variance matrixes for each class. The neural approach does not rely on statistical information derived from the sample data but is trained directly on the sample data; this is an important characteristic of neural methods because it makes no assumptions concerning the frequency distribution of the data. Statistical methods are known as parametric because they use statistical parameters that are derived from the training data, whereas neural methods are known as nonparametric (Mather 2004).

The supervised classification method requires prior knowledge of the number of classes and, for the statistical classifiers, some descriptive information from those classes is also required. Considering a remote sensing image, the statistical characteristics of the classes that are to be estimated from the training sample pixels depend on the method that will be used. The simple parallelepiped method requires estimates of the extreme values on each feature for each class, while the k-means or centroid method needs estimates of the multivariate means of the classes. The maximum likelihood algorithm requires estimates of the mean vector and variance matrix of each class. On the other hand, the neural classifiers operate directly on the training data but are strongly influenced by the mis-identification of training samples and by the size of the training datasets. The mis-identification of an individual training sample pixel may not have much influence on a statistical classifier, but the impact on a neural method could be considerable.

The a priori knowledge of the number and statistical characteristics of the classes should be reliable and this is a matter of crucial importance for a correct and accurate process. The accuracy of a supervised classification analysis will depend on two factors:

- The representativeness of the estimates of both the number and the statistical nature of the information classes present in the dataset.
- The degree of departure from the assumptions upon which the classification technique is based.

These assumptions may vary from one technique to another; however, the most sophisticated technique will have the most stringent assumptions. Moreover, the validity of statistical estimates depends upon two factors: the size and the representativeness of the sample. The sample size is not simply a matter of “the bigger the better;” it is related to the number of variables whose statistical properties are to be estimated, the number of those statistical properties, and the degree of variability present in the class.

As an example, considering a remote sensing image, in the case of a single variable and the estimation of a single property such as the mean or the variance, a sample size of 30 pixels is usually held to be sufficient. For the multivariate case, the size should be at least $30p$ pixels per class, where p is the number of features (e.g., spectral bands). The classification accuracy tends to improve as the sample size increases (Dobbertin and Biging 1996); therefore, depending on the computer performance available to the user, the sample size can be increased in order to obtain a more robust result. On the other hand, neural-based classifiers appear to improve its performance compared with the statistical approach for small training sets, though better results were achieved when training set size was proportional to class size and variability (Blamire 1996).

Training samples are normally located by fieldwork or from air photograph or map interpretation (for the sample of remote sensing images), and their positions on the image found either by visual interpretation, carrying out a geometric correction on the image, or by geopositioning of the image to be classified. Therefore, a map coordinate will be converted to the corresponding image in column and row coordinates; the location of the image of a training sample whose map coordinates are known is a relatively simple matter, providing the geometric transform is accurate.

The minimum sample size previously specified is valid only if the individual members of the

training sample are independent, as would be the case if balls were drawn randomly from a bag. Generally, adjacent pixels are not independent, for a remote sensing image for example, and if a pixel is identified as “forest,” its neighbor pixel would also be a member of the class “forest.” If those pixels were statistically independent there would be an equal chance that the second pixel was a member of any one of the candidate classes, irrespective of the class to which the first pixel was allocated. The correlation between nearby points in an image is known as spatial autocorrelation. It follows that the number of pixels in a sample is an overestimate of the number of fully independent pieces of information in the sample if the pixels making up the training sample are autocorrelated, which may be the case if a block of pixels is selected rather than scattered. The consequence of autocorrelation is that the use of the standard statistical formulas to estimate the means and variances of the features, and the correlations among those features, will provide biased results. Correlations between spectral bands derived from spatially autocorrelated training data will, in fact, be underestimated and the accuracy of the classification will be reduced as a result. The variance matrixes are considerably greater when computed from randomly selected pixels within a class rather than from contiguous blocks of pixels from the same class. The degree of autocorrelation will depend upon the natural association between adjacent pixels, the pixel dimension, and the effects of any data pre-processing. The degree of autocorrelation can be calculated by taking sequences of pixels that are spaced several units (predefined) apart and plotting the correlations between a set of pixels and their first, second, third, and subsequent nearest neighbors in the form of a correlogram (Basu and Odell. 1974).

Another source of error encountered in the extraction of training samples is the presence in the sample of atypical values. For instance, one or more vectors of pixel measurements in a given training sample may be contaminated in some way; therefore, the sample means vector and variance matrix for that class will be in error. There are some methodologies to detect those atypical values using estimators of the mean vector and variances matrix which are robust; that is, they are not influenced by those atypical values (Campbell 1980).

The performance of a classifier is usually evaluated using measures of classification accuracy. These accuracy measures use a test set of known data that are collected using the same principles as those described above for the training dataset. The training data are used to calibrate the classifier and test data are used for validation (Muchoney and Strahler 2002).

Statistical classifiers

Three algorithms are described in this section; all require the number of categories (classes) to be specified in advance and that certain statistical characteristics of each class are known:

1. The parallelepiped or box classifier, where a parallelepiped is considered as a simple geometrical shape consisting of a body whose opposite sides are straight and parallel. A parallelogram is a two-dimensional parallelepiped. To define such a body all that is required is an estimate for each class of the values of the lowest and highest pixel values in each band or feature used in the analysis. Pixels are labeled by determining the identifier of the box into which they fall.
2. The centroid classifier, which uses information about the location of each class in the p -dimensional Cartesian space defined by the p bands (features) to be used as the basis of the classification. The location of each class in the p -space is given by the class mean or centroid.
3. The maximum likelihood classifier, which also uses the mean as a measure of the location of the center of each class in the p -space and, in addition, makes use of a measure summarizing the disposition or spread of values around the mean along each of the p axes of the feature space.

Neural classifiers

One of the best image interpretation systems is the combination of the eyes and the brain. Signals are received by two sensors and are converted into electrical impulses and transmitted to the brain,

which interprets them in real-time, producing labeled and three-dimensional images of the view field. The brain is composed of a large number of simple processing units called neurons. The number of neurons is in the order of a hundred billion (Greenfield 1997), and each neuron is connected to around 10,000 other neurons (Beale and Jackson 1990). The neurons are connected in complex ways, so that each neuron receives as input the results produced by other neurons, and in turn outputs its signals to other neurons.

The artificial neural networks are based on this model of the brain by building sets of linked processing units in analogy with the neurons of the brain and using these to solve problems. Each neuron is a simple processing unit which receives weighted inputs from other neurons, sums these weighted inputs, performs a simple calculation on this sum such as thresholding, and then sends this output to other neurons. The learning process is accomplished by providing training samples and comparing the actual output of the artificial neural network with the expected output. If there is a difference between the two, then the weights associated with the connections between the neurons are adjusted so as to improve the chances of a correct decision and diminish the chances of the wrong choice being made, and the training step is repeated. This simple model is called a single layer perceptron and it can solve classification problems for pattern recognition applications.

Tripole (Ternary) Diagrams

ANTHONY C. KING

University of Winchester, UK

Tripole diagrams (also known as ternary or triangular graphs, and phase diagrams) are used in archaeology to aid analysis where three variables are compared with each other, within an equilateral triangle as the basic display medium. The graphical display allows for assessment of a large number of individual cases, either by simple visual means or by sectoral subdivisions within the diagram (Figure 1a).

In order to draw up a tripole diagram, the data need to be standardized, usually to percentages. This has the effect of making the three variables entirely interdependent, with significant implications for the choice of variable to be plotted and overall interpretation of the diagram. Graphing programs are commonly used for creating the diagrams and associated data tables, usually in the form of add-ons to Microsoft Excel, such as Tri-plot (Graham and Midgley 2000), or specialist graphing software, such as the ggtern add-on to R (Baxter and Cool 2016) or SigmaPlot. Traditionally but now obsolescent, printed triangular graph paper was used for hand creation of inked diagrams.

The selection of cases to plot in a tripole diagram needs to be carefully made. Standardization has the effect of giving each case equal weight, regardless of whether the underlying total for each case was very low or high (Steele and Weaver 2002). In practice, two procedures can mitigate this: (1) non-inclusion of any case with a total below a certain threshold (e.g., 200); and (2) use of a system of graded symbol sizes on the diagram to indicate each case total (Figure 1b).

Another issue in the selection of data is that the diagrams work best when all three variables are clearly present, in at least the majority of cases

in a sample. If not, for instance if two variables are dominant and the third only feebly represented, the resulting diagram will place all the cases along or adjacent to the margin of the triangle representing 0 percent of the third variable. This reduces the usefulness of the ternary effect in the plot, and two-variable graphing would usually be preferred.

Interpretation of a tripole diagram is, effectively, a visual process, that is, by observation of where cases cluster or disperse across the diagram. This is akin to examining an x/y scatter diagram visually for clustering, linearity, and so on, prior to further statistical processing. Usually, visual observation is as far as interpretation is taken, for most tripole diagrams, and interpretation takes the form of statements such as “the cases cluster towards the high X percentage sector of the diagram, thus confirming the dominance of X in the analyzed sample.” However, it is possible to subdivide the diagram into predetermined sectors or phases, for instance to define soil or chemical composition, and then to inspect the dispersion of cases and their fit within the various sectors. A more statistical approach is to define means and standard deviations for each of the three (standardized) variables in the sample, and plot the resulting polygon within the diagram. This can highlight differences between groups of cases from different samples plotted on a single tripole diagram. Alternatively, kernel density estimates can be added to the diagram (Baxter and Cool 2016, 126) or likelihood estimates plotted as curves/contours within the diagram (Weaver, Boyko, and Steele 2011).

Usage of tripole diagrams in archaeology is most commonly met with in zooarchaeology, especially where percentages of the three main Eurasian domesticated mammals are being compared—that is, domestic ox, sheep, and goat (usually grouped together), and domestic pig. Examples include comparison between provinces of the Roman Empire (King 1999), or temple assemblages compared with other types of site (King 2005, Figures 2 and 3).

Figure 1 (a) Tripole diagram of ox, sheep/goat, and pig assemblages from Roman Britain, with categorization of type of site. Source: King 1999, Figure 9. (b) Tripole diagram of cereal grains, chaff, and weed seeds from the Roman site of South Shields, the United Kingdom, showing proportional circles relative to the size of each sample, and enlargement of a portion of the diagram to enhance readability. Source: Van Der Veen 1992, Figure 8.4. (c) Blank tripole diagram for clay, silt, and sand percentages, showing a scheme of phases for definition of sediment types. Source: N. Hamilton, <http://www.ggtern.com/wp-content/uploads/2014/07/plot.png>.

Other uses within zooarchaeology include intrasite analysis of assemblages, mortality profiles (Steele and Weaver 2002; Weaver et al. 2011), and comparison of representation of body zones in a single species. In paleobotany, tripole diagrams have been used to plot grain:chaff:weed ratios in archaeological samples (Figure 1b).

Another common usage of tripole diagrams is in archaeometallurgy and chemical compositional analysis, for instance to compare gold, silver, and copper ratios in metal artifact surface composition (Baxter and Cool 2016, 127–129) or copper alloys (Roxburgh et al. 2016, 416). It was in this area of science that tripole diagrams were effectively first developed (Howarth 1996). A third area of application of tripole diagrams is in geoarchaeology, especially soils and sediment analysis, where it is used, for instance, as an aid in “finger-texturing” soil samples (Jones 2007, Figure 29) (Figure 1c). It is largely from these branches of the earth sciences that the impetus came for the take-up of tripole diagram methodology more widely in archaeology in the mid-twentieth century.

The advantage of creation of a tripole diagram is that large datasets with three variables can be displayed and samples easily compared. Attention, however, is needed in the selection of material to be compared in this way, because of the interdependence of the standardized data. Encouragingly, there are now increasing signs of utilization of this graphing technique in artifact assemblage analysis, as well as the archaeological science applications outlined above (Baxter and Cool 2016, 120–122).

Action Theory

ANDREW GARDNER

UCL Institute of Archaeology, UK

Overview

One of the central problems of archaeology as a “human science” is the nature of human action. What might be thought of as essentially sociological, psychological, or philosophical questions about human intentionality, individuality, socialization, and so on become distinctively archaeological when considered over the breadth of times, places, and societies that the discipline deals with. Two important aspects of these questions, from an archaeological perspective, are the degree to which there are universal modes of human engagement in the world, and the role that material culture plays in mediating or shaping the ways in which humans act. Each of these sets of issues in turn leads on to other crucial questions to do with the distinctiveness of humans vis-à-vis other species, and the ways in which seemingly inanimate entities—everything from the wind to a computer—can be said to “act.” Archaeologists need to consider such issues not only because the archaeological record is primarily a record of human action, but also because answering some of these latter questions has the potential to offer profound insights to a wide array of other disciplines. Thus, these sorts of issues frame much of the relevance archaeology has in the contemporary world. Like many such foundational issues, however, archaeologists have only relatively recently opened them up to serious debate; prevailing approaches for much of the history of the discipline were rather limited. The next sections review these earlier approaches before delineating the contours of current debate.

Early approaches to action in archaeology

The practice of archaeology in the nineteenth and early twentieth centuries lacked an explicit theory of human action, even though this period—in the diverse manifestations of Marxism and phenomenology, to name but two of the relevant intellectual movements—was the heyday of philosophical approaches that would later be highly influential. The most coherent and timely theoretical agenda in archaeology of the later nineteenth century was evolutionism, but this was very different in substance to later phases of evolutionary theory in archaeology, and dealt primarily with very broad social groupings rather than the details of individual activity. In the early twentieth century, with the coalescing of the “cultural historical” school of archaeology across Europe and North America, a more particularistic focus on the definition of individual cultures did develop. However, this again largely ignored the issue of human action as in any way problematic, instead defaulting to a “normative” view that people’s activities were implicitly characteristic of the ethnic or social group of which they were members. This developed in parallel with functionalist sociology and anthropology of the same period, which tended to stress forces promoting social conformity. The beginnings of an agenda allowing for freedom of action, and thus the role of human actors in creating social change, began to be evident in the Marxist-inspired work of V. Gordon Childe, but this did not flourish in the cultural climate of post-World War II UK and US archaeology (though it did elsewhere in the world). Rather, in the 1960s especially, an evolutionary approach reemerged, which paid some attention to the mechanics of human activities but primarily through the lens of what might be more or less adaptive *behaviors*. The significance of this latter term, as distinct from “actions,”

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

© 2018 John Wiley & Sons, Inc. Published 2018 by John Wiley & Sons, Inc.

DOI: 10.1002/9781119188230.saseas0005

is that it indicates an approach to interpreting human (or animal) activity with reference only to externally visible characteristics and thus without reference to “inner” thought processes (Shanks and Tilley 1992, 55–56). It is thus characteristic of the whole series of approaches considered so far which, in their own distinct ways, privileged “objective” entities—social groups, observable behaviors—over “subjective” ones. Only with the explicit introduction into archaeology of theories dealing with the latter, in the 1980s, can we say that the discipline began to deal with human action in a meaningful sense.

Agency debates from the 1980s to today

Much of the discussion taking place in archaeology since the beginning of the 1980s about the complexity of human action, and the relationships between thoughts, activities, social groups, and artifacts, has been conducted around one key term: “agency.” While its meaning is notoriously malleable (Dobres and Robb 2000), this word has traditionally been used in social theory to refer to the human capacity for action which is at least potentially intentional and knowledgeable—that is, involving some degree of free will, but also conducted in a context of socially established conventions of how to act appropriately. Embedded in this concept, then, is a cluster of complex issues to do with the nature of human consciousness and embodiment, as well as the connection between what goes on in an individual’s cognitive experience and the social world around them. While it is easy to characterize this as essentially a debate over individual freedom versus social determinism, a long tradition in social theory has sought to articulate the problem in more nuanced terms. Archaeologists began to incorporate some of this work into their theoretical frameworks in the 1980s, along with other related ideas about the meanings of material culture and the political dimensions of the past that, collectively, came to define “post-processual”/“interpretive” archaeology. Most prominent in the reference points for early explorations of agency, and its companion term “structure” (referring to social formations/institutions), were the works of social theorists Anthony Giddens and Pierre

Bourdieu, both working creatively with the traditions of structuralism and Marxism, among others. Both scholars, in distinctive ways, sought to understand the mutually constitutive relationships between “agency” and “structure” in shaping human lives. Both stressed the concept of “practice” as the medium through which these relationships unfold—the balance between individual volition and social influences being manifest in all human activities to different degrees. Archaeologists deployed these insights in various ways, though also soon began to develop and critique certain aspects of them. From the outset, there were debates not only about the intricacies of different models of human action, and the effectiveness of their archaeological application, but also about the key question of universality of human experience across time and space (Johnson 1989). Through the 1990s and into the 2000s, as archaeologists continued to work with agency, structure, and practice in detailed case studies while developing different views on this question (see, e.g., Dobres and Robb 2000; Gardner 2008), the general notion that past agency was an important topic began to become fairly mainstream. From this point to today, though, the terms of debate have shifted as challenges to practice-based approaches have emerged from two different directions: evolutionary theory and post-humanism.

Approaches in contemporary evolutionary archaeology are distinct from both of the earlier major phases in the development of this tradition in several ways, but most relevant here is their attention to processes of cultural transmission—the ways in which patterns of activities (e.g., pottery-making) are passed on over time. The preferred approach to modeling these processes is in terms of neo-Darwinian theories dealing with variation, selection, and adaptation. As a perspective on human action, therefore, this can perhaps be aligned with previous trends in archaeology which paid less attention to conscious decision making and more to underlying forces in driving the ways in which individual humans act. This has led to some significant debates between the interpretive and evolutionary schools in archaeology in recent years (e.g., Kristiansen 2004), which often recapitulate earlier post-processual–processual divides about whether particularistic/emic or generalizing/etic

interpretation is more fruitful or viable in archaeology. It is worth noting, though, that the way in which practice theories approach the largely unintended reproduction of social structures is somewhat similar to the notion that individual actions might also have long-term adaptive significance, and this reminds us that a crucial question in both approaches is the nature of the connection between small- and large-scale phenomena. However, a more challenging aspect of some evolutionary archaeology has been the suggestion that the units of selection (the “memes”) might be the real drivers of cultural change, with humans being mere vectors for the reproduction of pottery styles and the like. Interestingly, the idea that types of pots might have more “agency” in their transmission than the humans making them intersects quite closely with the other major emerging school of thought on action, inspired by quite different intellectual trends that can loosely be described as “post-humanist.” Like evolutionary archaeology, this is a diverse movement and incorporates work variously inspired by figures in anthropology (Alfred Gell) and science and technology studies (Donna Haraway, Bruno Latour), among others. The broad program is to overturn the purported anthropocentrism of previous archaeology and accord more “agency” (and/or “personhood”) to other species, and to the object world, often by distributing action among networks of entities (e.g., Gosden 2005). There are some further similarities here with evolutionary thinking, which also ultimately seeks to downplay the “specialness” of humans that more traditional social theories are said to assume (though this point is contested; see later). Since these post-humanist/“new materialist” approaches have advocated a distributed or generalized model of agency, it seems that future directions in this area will be defined, as they were 20 or so years ago, by the question of what does—or should—“agency” mean?

Future directions

Theories about human—and nonhuman—action address central problems in our understanding of the past and relate quite crucially to the role of archaeology in the present. They connect the

discipline to a wide range of other fields across the social and biological sciences. Necessarily, therefore, it is unlikely that some of the major debates touched upon here will be definitively resolved at any point soon. There is considerable scope for new alignments in archaeological theory to replace those that have dominated the discipline since the 1960s, based on some of the conjunctions mentioned above in evolutionary and “new materialist” approaches. There is also great potential for some as-yet untapped theoretical traditions, such as the pragmatist/symbolic interactionist school of social theory, to find fuller development in archaeology (Baert and Carreira da Silva 2014). Yet it remains necessary to keep debating the core issues and identifying the strengths and weaknesses of different traditions without oversimplifying or caricaturing different positions, something that has unfortunately dogged theoretical discussion in archaeology since the 1960s. At the time of writing, some of the claims of the “new materialist” approaches about “humanist” archaeologies of agency are being challenged or rebutted (e.g., Barrett 2014; Ribeiro 2016), and this debate, rather than the creation of a new orthodoxy, is probably healthier for the discipline. Indeed, archaeologists could do worse than apply different theories of action to themselves and to the creation of knowledge in contemporary contexts of practice, to enhance disciplinary reflexivity and consider how archaeology might most effectively develop in the future.

Archaeological Fieldwork

MARCUS W. R. BRITTAIN

University of Cambridge, UK

Fieldwork is practical research conducted in the context of a site or a landscape. It is multidisciplinary and comprises a range of techniques and methodologies that may be utilized in the identification, recovery, and recording of archaeological data. Archaeological fieldwork is most often directly equated with excavation—a range of techniques that provide an intrusive entry into an archaeological resource, and which is perceived to distinguish archaeological fieldwork from that pursued in other sciences. However, there are a multitude of non- or less-intrusive techniques in archaeological fieldwork (such as differing forms of ground or aerial survey) that share methodological bases (and origins) with other sciences.

Fieldwork is a blend of investigative standards and innovative practice. Commitment to a methodological strategy, for example, may require recognized techniques modified as appropriate to particular circumstances of fieldwork, such as in response to the characteristics of a site's topography and its geology; the quality and scale of archaeological preservation; the logistics of a site's geography, including its sociopolitical context; and the nature and scale of a project's specific research priorities, expectations, and financial resources. Basic methods remain similar to the origins of fieldwork, but are greatly enhanced by the depth and detail of scientific techniques and experience of expertise. The relationship between fieldwork (as the recovery of data) and theory (as the interpretation of data) is conceived in a number of ways that, rather than simply reflecting historical advancement across the discipline, are a result of the multiplicity of conceptual frameworks through which archaeology is practiced and understood today.

The origins of fieldwork as a practice performed by scientists may be found in the

activities of naturalists and geologists in the later nineteenth century, as well as in antiquarian studies. Similar to the collection of specimens, excavation was simply a recovery method for items of material culture and supplemental to topographic survey. Disciplinary advancement emerged through analysis of collections by individuals not necessarily engaged in the attribution of specimens through fieldwork. As a consequence, a broad distinction emerged between the intellectual pursuit of collections and the practical collation of specimens in the field. Where written records may not have sufficed, the cultural progress of humanity could be traced in the stylistic and typological developments of material collections; understanding the evolution of human society owed little to the specific qualities and character of individual sites.

Archaeological conceptions of human cultures through principles of evolution may account for the limited status assigned to fieldwork in the nineteenth century (Lucas 2001). Emphasis was instead placed upon material collections and their classification into a universalized scheme. Emergence in the early twentieth century of a particularistic conception of human cultures, such as the historical assemblage of areal cultural groups, established the importance of objects' spatial and temporal context, and thereby enhanced fieldwork as integral to archaeological analysis. Primary to the concern of culture history were questions of what, where, and when? Greater standardization of data collection via fieldwork was a requirement for comparison of material assemblages across cultural groups. It is therefore not coincidental that in the first half of the twentieth century a growing number of field manuals emerged that defined standards and methodological principles required for scientific archaeological fieldwork. By the 1960s, the solidity of these principles and the questions for which they were developed underwent a radical transformation, most notably as a part of the "new archaeology" (or processual archaeology) in which fieldwork was aimed towards questions concerned more with how and why cultural changes take

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

DOI: 10.1002/9781119188230.saseas0027

place, rather than simply recording the traits that determine cultural definition. Advocates of this approach argue that archaeological data from particular regions contains information necessary to identify and to study the complex systems behind cultural processes, such as regular patterns of behavior; however, the visibility of relevant information is inhibited by a lack of statistical control during fieldwork (Binford 1964). Isolating the kind of data required to solve this problem may therefore be achieved via appropriate sampling strategies designed specifically for hypothesis testing against the immediate and unique circumstances of data recovery. This is a reflexive process in which feedback from data analysis leads to the modification of the sampling strategy during subsequent fieldwork.

To the philosophical traditions of culture history and processual archaeology common methods and aims are desirable to the development of a unified discipline in which data recovery might facilitate intersite or cross-regional comparison. Indeed, many of the principles that have emerged from this goal lie at the core of field research design. Ideally, this is a structuring framework conducted with a procedure that includes reconnaissance (survey and background research), evaluation (intrusive sampling for site characterization), strategy planning and excavation (method of data identification and recovery), and analysis of data upon which future strategies may be modified (Carver 2011).

Across a number of European nations, as well as North America, Australasia, and Japan, the majority of archaeological fieldwork has functioned within the framework of development and its attendant planning legislation. This is a reactive process, carried out in response to individual development, and requires assessment of the archaeological character and significance of the area affected by a proposed development and the likely impact that this may incur. This has led to numerous and major archaeological operations, sometimes on a substantial scale. In general, the same procedures of field research design outlined above are implemented, but the exposure of enormous areas far greater than was previously possible has allowed for detailed reflection as to the success of evaluation and sampling methodologies.

Owing to the competitive nature of open-tender contracts in development-led archaeology, pragmatic constraints often posed by limited time and financial resources, and perhaps also as a response to its expanded professional status, a degree of standardization in fieldwork methodology has emerged. On the one hand, this provides a baseline against which to adjudge the quality of archaeological investigations; on the other hand, sampling strategies designed to locate the anticipated presence of particular features of a site are constrained with bias towards these types of site. Instead, by employing a spirit of experimentation and innovation, particularly in sampling exercises, fieldwork may with greater accuracy determine the appropriate levels of work required on these sites.

A recent example of experimentation and refined sampling methodology is found in Cambridgeshire's fenland in the United Kingdom (Evans, Tabor, and Vander Linden 2014). This comes from a large decade-long investigation of a series of small riverine islands sealed by thick overlying strata, excavated in advance of their destruction by aggregate quarrying. In this situation, particular conditions of burial had ensured that archaeological deposits survived in great quantity in sealed paleosols (ancient land surfaces) and overlying ploughsoil. The scale of these residues presented challenges of strategy and prioritization. Whereas cut features were comparatively limited in their numbers, tens of thousands of artifacts were encountered throughout the thick, sealed paleosol. Differing complementary techniques were employed at different stages of the fieldwork in light of incremental experience gained in ongoing methodological experimentation. This was not simply employed to achieve maximum data recovery (total recovery would have been an impossibility, given the scale of the finds numbers and ground coverage compared with available resources); the aim was to answer specific questions so as to avoid the repetition of preformed assumptions about past behavior and long-term cultural development. In this instance, where the scale of past activity is matched by the intensity of investigation, a distinct "narrative" was gestated during the immediacy of fieldwork, and ultimately framed by particular ways of (and reasons for) thinking and doing.

Reevaluation of fieldwork has, since the 1990s, centered upon the connection between theory and practice, or thinking and doing. Like the example above, this has expanded upon discussions concerning sampling in fieldwork and its implications to an understanding of archaeological data by problematizing the assumption that fieldwork is an objective activity and that its primary function is the acquisition of data separate from and prior to the processes of interpretation and writing “narratives.” Drawing insight from philosophies of science, two important themes have emerged in contemporary debates concerning fieldwork: (1) First contact with the material traces of the past takes place within the field and is an interpretative practice; and (2) fieldwork takes place in, and is a part of, a material world that channels practices of interpretation. These themes are outlined below.

A key aim has been to foreground fieldwork as a practice and an experience that has a significant—indeed, founding—role in the production of knowledge. The fieldworker is foregrounded as central to this reevaluation, and viewed as partaking in a dynamic and subjective encounter with residues of the past (Hodder 1999). In the immediacy of this encounter, the fieldworker’s craft greatly relies upon a developed sensory register that is learnt through practice, such as an ability to “read” the traces of past occupation in a landscape’s lumps and bumps, anticipating a subtle change in a soil deposit through its appearance and the texture of the grain, or recognizing material by its weight, size, and form. Such skills develop over time and through experience, and are applied together with a multitude of factors (e.g., related deposits and other archaeological features; the accumulation of data from elsewhere on a site) to make informed judgments that determine what is archaeological from the nonarchaeological, and to distinguish relevant data from what is often highly fragmented and mixed traces.

Highlighted in contemporary philosophical debates concerning fieldwork is that archaeological data is not necessarily predetermined prior to its recognition in fieldwork, awaiting its discovery. This challenge emerged from a broader concern in post-processual archaeology: that knowledge is not discovered out of neutral evidence, but is instead a product of social and

political conditions through which the practice of archaeology is constituted. According to this principle, fieldwork is not simply an exercise in data recovery and collection, but by mobilizing an assembly of different material bodies and agencies it is active in the production of data (Lucas 2012). Within these contemporary views of fieldwork, the production of data is contingent upon innovation in the strategies, techniques, and technologies available for their identification, recording, and recovery.

Another example of large-scale investigations in the United Kingdom illustrates the integration of a number of these principles at the heart of field research design. Carried out before the construction of a new terminal at Heathrow Airport, fieldwork was conceived around the premise that changes in material conditions at any given location made the living of varied kinds of life a possibility (Andrews, Barrett, and Lewis 2000). Communities across time inhabit places that already have a history with which past communities would have had to contend in different ways at different points of time. This was a driving theme throughout the field research design. During fieldwork, excavation staff worked with an integrated site database examining historical changes of the “natural” and “built” environment, and the character and effect of long-term formation processes on these, as well as the material expression of human response to the accumulation of these factors. The field research design facilitated preliminary and rapid site-based analysis and feedback and the development of a site “narrative” through field-based interrogation that could be further refined through off-site analysis: a dialogue between on-site and off-site analyses. Accepting the fragmentary nature of the archaeological record and the status of data as a product of interpretation, the visibility of data redundant to the emerging narrative could be defined.

An accompanying argument to the production of data through acts of interpretation is that the fieldworker is bound within the larger assemblage of material and conceptual entities, and is materially constituted as a field practitioner by an ability to mobilize an array of tools for recognition (trowel, toothpick, brush, etc.), measurement (measuring tape, grid peg, electric distance meter, etc.), and recording (pencil, camera, 3D scanner, etc.) of archaeological data. These materials are

part of a broader collective, the status of which, and their relationship to archaeological narrative, may differ depending on their combination and on their context of assemblage. The site archive has been provided as a particular example of this, and a further illustration of the material world relevant to fieldwork (Olsen et al. 2012). In this frame, the archive is the stabilization and collation of an otherwise fragmented record by means of a range of media, such as digital and film photographs, soil and organic samples, drawn sections and plans, digital spatial data and imagery, finds, and accompanying paper registry, including notes, diaries, and correspondence. The archive may be regarded as a representation of a site or the act of fieldwork, or it may be described as a “translation” (Lucas 2012); that is, the replacement of one material entity (a potsherd within a pit, for example) with another material form (a digital or hand-drawn plan and drawn section with photographs of the pit, along with a washed potsherd, perhaps illustrated, bagged, numbered, boxed, and catalogued in a register). As a dislocation of things from their context of discard and discovery, the archive may be regarded as a process of loss; but in viewing the archive as a material entity in its own right, the process of dislocation during and after fieldwork may also be viewed as the inscription of new meaning open to interpretation.

Fieldwork is a collaborative operation that involves a collective of people, materials, instruments, settings, and agencies. These combine to both enable and constrain the conduct and remit of fieldwork, and perhaps also in some cases the direction of fieldwork narrative. Differing agencies may authorize, accredit, and legitimize fieldwork. Permissions, standards, guidelines, and financial commitments are implicated in the fieldwork process via consultation with communities, local authorities, government ministries, heritage bodies, donors, lenders, or grant-awarding bodies, as well as academy and industry representation. Fieldwork is therefore not practiced outside of society, but is firmly integrated with the complexities of its problems and possibilities.

As much as fieldwork is conducted within the network of broader society, so too is it a social practice that encompasses a collective of multiple voices. The use of new media, onsite databases,

and individual field diaries has been integrated into a number of field research designs as a means to record processes of interpretation and documentation, both of individual and collective fieldworkers, these ephemeral moments otherwise being lost. Highlighting the collaborative nature of fieldwork entails an ethical motive, aimed towards a democratization of the interpretative process, from the ground up. The issue of multivocality in fieldwork has strengthened the growth of community-led initiatives that have emerged through concerns regarding the social value of archaeology and the ownership of narratives about the past, particularly in local settings. Development of these issues in field research design has benefitted greatly from postcolonial discourses. These have focused upon the value of fieldwork in contexts where local participants belong to cultural backgrounds notably different and largely incommensurate with that of the fieldwork team. A range of narratives arising by host and guest during fieldwork may reflect different views on the nature of heritage or distinction in the value placed upon archaeology and the priorities to which it may contribute.

An example of fieldwork conducted with one of Kenya’s Samburu communities illustrates an instance in which collaboration that embraces such differences of view can lead to innovative outcomes of knowledge production (Straight et al. 2015). This comprised the excavation of a stone burial cairn by a team of international scientists and the local community, structured through a triage study of cultural, biological, and archaeological anthropology. It was found that the event of the excavation itself, as well as the gradual revealing of the site’s excavated contents, inhabited a range of competing priorities among the team and the broader community and, importantly, generated a variety of open-ended narratives, included in which was the challenge of articulating the complexities of the fieldwork in a range of formats, including publication.

Archaeological Record

GAVIN LUCAS

University of Iceland, Iceland

The recurrent use of the term “archaeological record” may have originally come to archaeology via geology and paleontology, although in the nineteenth and early twentieth century a variety of terms including both “source” and “record” were used interchangeably. Indeed, the transference of more broadly literary or textual concepts to characterize all histories from the earth, including archaeology, was common practice in the nineteenth century. Referring to material remains—whether fossils, rocks, or artifacts—as documents, archives, testimonies, records, and sources was a standard device and one which remains with us today. Yet within nineteenth-century archaeology, there remained a tension between an archaeology which drew its legacy from antiquarianism and history and an archaeology which was more closely aligned with the emerging sciences of geology and paleontology. This division more or less mirrored the division between a historical archaeology which drew its framework from the written sources (i.e. biblical, classical, and medieval) and the new prehistory, the latter of which opened up deep time and brought in the three-age system. Although no longer oppositional as they once were, this division still arguably influences the current topography of archaeology.

It is against this backdrop that we can understand the two major conceptualizations of the archaeological record as they exist in archaeology today: source criticism and formation theory, both of which crystallized as distinct bodies of theory in the 1950s, though both of which had roots extending deep into the late-nineteenth century. *Source criticism* emerged most strongly in Central Europe and Scandinavia and was pioneered by the German archaeologist Hans Jürgen Eggers (Härke 1997; Kristiansen 1978; 1985). He drew explicit analogies between archaeological

finds and documents and, following source criticism in history, distinguished between external and internal criticism. The former, also called textual criticism, concerns the transmission of the source and its representativity, which archaeologists can control to some extent through fieldwork and sampling methodologies as well as attention to issues of preservation. Internal criticism however, was for Eggers of much greater concern because it pertained to historical interpretation. He argued that archaeological evidence was not a face value reflection of people's everyday behavior in the past but was often mediated by their beliefs and ideology and could thus give a false impression if read as such. Internal criticism is also linked to another key distinction in source criticism, between accidental and intentional sources (Härke 1997).

Formation theory in contrast is largely a North American development and is conventionally traced back to the work of Robert Ascher, who characterized the problems facing archaeology as twofold: missing evidence and how to interpret what does survive. However, it is Michael Schiffer who is most associated with the development of formation theory (Schiffer 1987). Schiffer's approach moved beyond the simplistic reductive view of formation processes, as exemplified in Ascher's theory. In that view, the problems were often perceived as largely quantitative—i.e. a loss of data—whereas Schiffer was arguing for the importance of qualitative changes to the record, largely due to differential discard practices and post-depositional processes. Such processes are not solely reductive but also additive and can introduce new patterns into the record. Schiffer catalogued an extensive array of such processes in his work, which he also famously divided into cultural and natural; or c- and n-transforms. In many ways, formation theory has retained its focus on the issues first identified by Schiffer, particularly processes of abandonment and discard or processes which delayed discard, such as curation and use-life (Shott 1998).

The distinction between these two traditions of thinking about the archaeological record should

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

not be confused with the distinction between a physical and textual model of the archaeological record proposed by Linda Patrik in her key paper on the topic (Patrik 1985). The physical model, according to Patrik, asserts that there is a causal and physical connection between past events or processes and the record itself—the prototype being the fossil record. The textual model on the other hand asserts that the record encodes information about the past, the prototype being a historical document. Patrik's paper was largely a review of the then current theoretical positions in Anglophone archaeology, the two models reflecting the different perspectives of processualism and post-processualism respectively. While the physical model can be equated with formation theory, the textual model only vaguely maps onto source criticism and there was certainly no genealogical link between the two. Patrik's review paper however is interesting on other grounds, particularly for highlighting the various meanings of the term "archaeological record" as used in the literature. She identified five different meanings used by archaeologists. The first is the material context in which past events or processes occurred—in short, what is variously called the "ethnographic past" or the systemic context. The second and third meanings refer respectively to the material deposits and material remains left behind by these past processes; the fourth concerns the part of these remains recovered by archaeology (i.e. the sample) and the fifth, the record archaeologists themselves create of these remains (i.e. archives, reports).

In many ways it is the interrelations between all these meanings that is significant and is the basis of Lucas' in-depth study of the archaeological record (2012). His book condenses Patrik's list from five to three and examines the productive tensions of juxtaposing the threefold idea of the archaeological record as material culture, as traces or residues of past events, and as the archaeological work conducted on those traces. Drawing on a diverse body of contemporary theory from actor network theory to the new materialism, Lucas argues that what holds these three different dimensions of the archaeological record together is processes of materialization and dematerialization. Lucas' subsequent work also explores other tensions and divisions within our understanding of the archaeological record,

notably the distinction between concepts of the fragment and the residue (Lucas 2014).

Various words have been used to characterize the nature of the archaeological record: remains, vestiges, ruins, relics, traces, and fragments. The list could go on, but by looking at the words we use to define the stuff that makes up the archaeological record in this generic sense, one can discern an underlying tension between two broader concepts, that of incompleteness and that of untimeliness. The idea of the archaeological record as incomplete or fragmentary runs through archaeological discourse since the inception of the discipline (Burström 2013) and its origins can perhaps be traced to Romanticism and art history through the concept of the ruin. The power of the fragment lies in evoking or underlining an absence or loss and, as such, initiates a discourse on the relation between the fragment and the missing parts or between the fragment and the whole. Now, of course, this is inevitably entwined with time, but by emphasizing the fragmentary, time is colored in a very specific way and is conceived as a gradient of diminution or reduction. The whole pot reduced to a few sherds, the pristine sword corroded to a rusty, flaky stick of iron. Indeed, precisely because these are strongly material properties we can directly experience, it is perhaps unsurprising that they are metaphorically extended to define the whole archaeological record.

Arguably the idea of incompleteness has very much dominated our conception of the archaeological record since the late-nineteenth century. Classic statements of this conception emerged in the middle of the twentieth century—formation theory, sampling theories, and source criticism, all of which stressed the loss of evidence or data in the form of a failure to survive—whether this is organic materials or ephemeral phenomena like behavior itself. Moreover it is not only the nature of the archaeological record that is conceived primarily through the notion of the fragment, it is also the nature of archaeological practice. The idea of practice being guided by incompleteness is evident throughout the history of the discipline through the ideal of the total record. Beginning in the late-nineteenth century with German classical archaeology, which stressed the need for a full recovery of all remains not just the fine art specimens and the aspiration for complete collections

of material for analysis, these ideals carried through into the late-twentieth century and its idealization of the archive objective—that the archive should stand in for the site itself. Of course the ideal of the total record was always ambiguous and perhaps seen as an impossible ideal. Yet this ambiguity played to the heart of the issue of incompleteness because it was always about mediating the relation of fragment to whole.

While the idea of incompleteness and the metaphor of the fragment is a powerful way to think about the archaeological record, it lacks an integral temporal dimension. This is not to suggest it cannot be aligned with time, only that time becomes secondary and therefore mediated by the idea of incompleteness, hence the dominant connotation of loss. By contrast, terms such as residues, relics, or vestiges conjure up a rather different image of the archaeological record. Such remains may indeed even be complete or whole; what defines them is not so much their incompleteness but their *untimeliness*; they are from another era, anachronisms, survivals. This conception of the archaeological record in fact may have been the more dominant one in the nineteenth century, only superseded in the twentieth by the metaphor of the fragment. Such a view is very clearly expressed when one considers the close relationship that existed between material remains and what came to be called survivals, that is extant customs or practices which no longer have any obvious purpose, like vestigial organs. In fact up to the middle of the nineteenth century, the word *antiquities* was commonly used to refer to both.

What makes relics and survivals significant then is their *non-contemporariness*. This articulation through the concept of the contemporary is very apposite because it immediately resonates with the oft-repeated statement that the archaeological record is a contemporary phenomenon. This contradiction is particularly troubling, for on the one hand, archaeological remains *are* contemporary—they exist here and now and they are what we engage with, even if our objective is to wrestle out a story about the distant past. At the same time, they are also of or from the past, and not simply in the sense of having persisted or endured in a neutral, chronological sense, but they have persisted into a time in which they do not seem to belong. That is the crux of the

concept of survival: an anachronism, an object or custom out of its proper time. Of course this begs the question of what constitutes the “proper” time for an object and no doubt archaeology itself has helped to create the perceived proper temporal order for things, but more generally this is probably the legacy of modernist thinking insofar as the trope of modernity defines the very possibility of something being untimely. What it underlines though is the way time is critically implicated in our understanding of the archaeological record and how we conceptualize time deeply affects how we think about that record.

Archaeologies of Technology

BRIAN BOYD

Columbia University, USA

“Technology reveals the active relationship between man and nature, a direct process of his existence, consequently of the social relationships of his life and so of the general spiritual phenomena that arise from them” (Marx 1867).

“Technology is a science, and because technical facts are facts of human activity, it is a human science, a branch of anthropology” (Sigaut 1994, 422).

Technology—as distinct from *techniques*—may be the material artifacts that humans and some nonhuman animals make and use, the built architecture with which they embellish spaces and places, and in which they dwell and work. It may be also the various ways and means through which people and animals communicate, both oral and written, and the digital media technologies—as representation-based languages—that are embedded in the global technologies of modern capitalism. Some societies routinely engage technologies of conflict and violence, technologies of political and religious authority, and modern reproductive technologies that intervene in the biological cycles of humans, animals, and plants. All these forms of technology are integral to social life in order to facilitate particular actions and practices, to enable discourse. The extent to which social life takes place through technological means has long been a focus of science and technology studies (“the turn to technology”). The theoretical significance of these debates to sociocultural anthropology and archaeology has become increasingly apparent.

For archaeologists, defining technology is not as straightforward as it was in the days of functionalism and culture history. Since the mid-nineteenth century publication by Boucher

de Perthes concerning the first Paleolithic tools (hand axes) found in the Somme river valley, France, the material residues of past technological practices were regarded as more or less self-evident and easily understood through inferential thinking. For example, discussing his “ladder of inference” approach in relation to prehistoric technology, Christopher Hawkes argued: “To infer from the archaeological phenomena to the *techniques* producing them I take to be relatively easy. The modes of research are themselves no doubt difficult, and in detail often tedious. But the reasoning employed, I maintain, is basically simple” (Hawkes 1954, 161). In other words, the connections between the observed material record and the past processes that produced that record are relatively unambiguous because they can be inferred through uniformitarian assumptions about the nature of the relationship between process and residue. A basic example of this is the relationship between the physical properties of flint that allow knappers to predict accurately specific fracture patterns, and the resulting composition of debris and debitage left by the knapper’s actions. Through this assumption of uniformitarian predictability, past manufacturing techniques can be studied through, for example, the experimental replication of stone and bone tools, pottery, and other objects. The publication of Russian archaeologist A. A. Semenov’s *Prehistoric Technology* (1957, trans. 1964), which combined such replication experiments with contemporary ethnographic observations and the microscopic analysis of artifact surfaces (use-wear), allowed archaeologists to observe and describe techniques of artifact manufacture and use. This general methodological approach to past technological processes resonated well with Lewis Binford’s influential ethnoarchaeological research into modern hunter-gatherers, which examined the technological processes by which humans manufactured stone tools, and procured, killed, and butchered animals. The material culture patterning generated through these technological activities allowed Binford to make inferences about past human behavior and animal exploitation strategies.

While this approach opened up a new field of hunter-gatherer technology-related research, it was criticized at the time for being entrenched in problematic uniformitarian assumptions. So, while the new/processual archaeology shifted the discipline's methodological parameters on technology by moving into ethnoarchaeological inquiry, the primary focus remained, as with the culture history approach, on the purely utilitarian, mechanistic aspects of technology and material culture. In this way of thinking, technology/material culture was analyzed as a subsystem or component—alongside economy, religion, social structure, and so on—within the totality of the larger sociocultural system.

It has been argued that a conceptual break with the cultural historical and processual views of material culture/technology as an “extrasomatic means of adaptation” was marked by the early 1980s advent of post-processual archaeology. In an article first published in 1989, Christopher Tilley argued that the conception of material culture as a system of signification largely came about through (mainly British) archaeological theory's encounter with elements of linguistic and anthropological structuralism, first discussed in any detail in Ian Hodder's 1982 edited volume *Symbolic and Structural Archaeology*. Tilley focused on the potential for material culture analysis of Saussure's early-twentieth-century structural linguistics, which distinguished between *langue* (a system for conveying meaning through rules and functions) and *parole* (speech, the individual use of language) to reconceptualize archaeology “as being a pursuit of sign systems” (Tilley 1989, 188). The analogy with language and linguistic structure not only allowed material culture to be “regarded as a kind of text, a silent form of writing and discourse” (one of the key tenets of post-processual archaeology), but also emphasized that material culture is always a *social production*, not merely an adaptive mechanism or function. In other words, material culture was seen as “active” in the reproduction of social relations. While the textual/linguistic analogy facilitated a more nuanced consideration of the social production (and context) of material culture, conceptualization of technology as embodied practice remained relatively absent in early post-processual writings.

Conversely, French researchers of ethnology and prehistory had already situated material culture and technology within the realm of the “social body.” Drawing upon the earlier sociological and anthropological concepts of Emile Durkheim (the thing as a “social fact”) and, in particular, Marcel Mauss's “*techniques du corps*” (1935), the ethnologist/prehistorian André Leroi-Gourhan (1911–86) placed technology in the context of bodily gesture and knowledge. Mauss's “*techniques du corps*” recognized that technologies were embodied “social facts” (after Durkheim), shaped and influenced by social traditions (Mauss presciently described this relationship as “*habitus*”). Leroi-Gourhan developed this approach to tools and techniques in two books published in the early–mid 1940s, *L'Homme et la Matière* and *Milieu et Techniques*, but his major contribution to archaeological technology studies came twenty years later with the structuralist-influenced two-volume *Le Geste et la Parole. Technique et Langage* (1964), and *Le Geste et la Parole. II. La Mémoire et les Rythmes* (1965). In these works he detailed the proposition that “the tool really only exists with the gesture which renders it technically efficient” (1965, 35). That is, the artifact is animated by the gesture, a conception that formed the basis for Leroi-Gourhan's key contribution to technology studies, the *chaîne opératoire*—the sequence of embodied technical practices which transforms raw material into an artifact.

Leroi-Gourhan's work on techniques and technologies was, and continues to be, hugely influential in archaeological technology studies, particularly in the French-speaking academy. His 1940s–1960s technology research was mainly in the field of ethnology, but it was soon embraced by French anthropologists and archaeological prehistorians in the late 1970s, so much so that it seems reasonable to talk of a “French school” of prehistoric technology. Aside from his well-known structuralist analysis of European Upper Paleolithic cave paintings, his work on technology made little impact on English-speaking archaeology until the early 1990s, when an issue of the graduate student-edited journal *Archaeological Review from Cambridge* entitled “Technology in the Humanities” (Schlanger and Sinclair 1990) published in English a number of articles by key

authors in French ethnological and anthropological/archaeological technology studies—Robert Creswell, Pierre Lemonnier, Jacques Pelegrin, Nicole Pigeot, and Valentine Roux, as well as critical reflections on the work of Leroi-Gourhan himself. There followed the first English translation of *Le Geste et la Parole*, appearing as *Gesture and Speech* in 1993 (translated by Anna Berger).

With the *chaîne opératoire* now seen by some researchers as an analytical tool “as basic in prehistoric technology as elemental analysis is in chemistry” (Auduze 1999, 167), archaeological technology studies moved to a new prominence in various aspects of archaeological theory in the 1990s and early 2000s. Notably, Joan Gero brought archaeology’s relatively recent concern with gender to bear on questions about the long-assumed dominant role of men in the production of stone tools in prehistoric contexts. In her 1991 article “Genderlithics,” Gero drew attention to the hitherto unacknowledged role of women in such technological practices. Taking this critique further, and engaging current archaeological approaches to social agency and practice theory, Marcia-Anne Dobres (2000) noted the shortcomings of the *chaîne opératoire* approach when it came to the discussion of embodied and gendered agency. Although the concept refers to the relationship between materials and body practices, the latter were only formulated in terms of gestures and actions. Mid-1990s cognitive archaeological approaches drew attention to the cognitive knowledge and decisions that informed/structured such gestures and actions, as discussed earlier by Leroi-Gourhan, but fell short of conceptualizing the human body as the basic frame of reference in technological acts. Dobres, and others, further developed this general theory on technology—the relationship between techniques as the gestures and movements involved in artifact production and use, and the cognitive decisions, perceptions, and knowledge drawn upon and brought to bear on the execution of those techniques—but now situated it within a framework where the gendered body and embodiment were the central sites of technological practice. This perspective—the socialized, corporeal, and mindful body as the very essence of technological practice—aligned well with several post-structuralist archaeological approaches, sharing influences from key works

by Heidegger (*The Question Concerning Technology* (1982) and “being-in-the-world”), Foucault (“the political technologies of the body”), and Merleau-Ponty (technology as a “primary experience” of the body), among others. Postcolonial archaeologies are also now paying attention to nonwestern perceptions of matter, materials, and technologies, and to the political implications of challenging dominant western interpretations of such phenomena (e.g., Kusimba 2009).

In much current archaeological thinking, past technologies are often implicitly conflated with “material culture” in discussions of materiality and object ontologies. The influence of the *chaîne opératoire* still can be seen (although rarely cited) in notions of “object biographies” (e.g., Gosden and Marshall 1999) and the “life histories” of artifacts, approaches that take as a primary influence the sociocultural anthropological work of Appadurai, Kopytoff, and others on the historical networks of relationships between people and things, to demonstrate how the social biographies of objects are intimately entwined with those of the people who make, use, and exchange those objects. But some would argue that consideration of “social technologies” goes far beyond “things”—even “things” as conceptualized by recent post-humanist and new materialist perspectives. In the western industrial context, at any rate, technologies of the body and embodiment now range from cosmetic surgery, gender identity “realignment,” and intervention in the reproductive cycles of humans and nonhumans alike, questioning western biological definitions of humanity and the relationships between the human and the nonhuman. Perceived boundaries between the body, the self, and genders, synthetic and organic, are being subjected to radical, intimate enquiry by social technologies, and as students of such technologies, past and contemporary, archaeologists face new conceptual challenges in the definition of their object of enquiry.

Archaeology and the Present

CORNELIUS HOLTORF

Linnaeus University, Sweden

MATS BURSTRÖM

Stockholm University, Sweden

Archaeology in contemporary society and popular culture

Archaeologists in contemporary society are first and foremost known to conduct scientific excavations, and archaeology's widespread emblems are the spade and the trowel. But archaeology's continuing existence and general popularity does not only derive from its widespread scientific reputation and is at least as much due to the inspiring and sometimes inciting stories, popular entertainment, and fitting metaphors it provides in everyday society—going far beyond the realities of professional archaeology.

The appeal of archaeology in contemporary popular culture has long been derived to a large extent from prominent archaeological tropes such as the adventure of fieldwork, the discovery of treasure underground, the aura of the genuine thing, the detective-style analysis of the evidence, the revelation of insights and truths about the past, and the care given to the fragile archaeological heritage in the present (see *ARCHAEOLOGICAL FIELDWORK*). These tropes can also be applied to many other situations and contexts, and when this occurs, archaeology can acquire metaphorical significance. Authors such as Agatha Christie, Seamus Heaney, and August Strindberg; artists like Richard Long, Anne and Patrick Poirier, and Mark Dion; and a range of academics including Sigmund Freud, Walter Benjamin, and Michel Foucault have all drawn on archaeological tropes without actually being interested in literally working as archaeologists. Archaeology as a theme also occurs prominently in the visual arts, science fiction literature, adventure movies, games,

themed environments, and a large variety of other cultural genres and formats. Often archaeology becomes significant in all these contexts through its association with what lies below the surface, excavation, stratigraphy, traces of the past, treasure, analysis of material culture, and the act of remembering (Holtorf 2005). Archaeology can entertain and engage, provoke and disturb its audiences (see *PUBLIC ARCHAEOLOGY*).

Archaeologists who mention their profession to others are sometimes met with incredulity and the revelation that the conversation partner, as a child, also had entertained the dream of becoming an archaeologist—finding treasure and reconstructing the past—but that life had subsequently taken other turns. Scientific archaeology is however accessible to lay people not only by consuming popular culture but also by taking part in schemes through which they can participate in archaeological fieldwork. The demand of archaeological stories and experiences in contemporary society is, however, not only met by professional archaeologists but mostly through products and services offered by designers, film directors, tourist managers, public relations specialists, journalists, and many others. In all these ways, archaeology can not only directly enhance the quality of peoples' lives but also provide for the living of professionals who have no formal links to the academic discipline.

A variety of increasingly sophisticated scientific practices and approaches allow archaeologists to translate the particular material remains and topics they study into a rich array of stories that are about the past and/or about archaeology itself. Archaeological stories often engage with the big questions of what it means to be human; what human life was like in other periods; who we are, where we are coming from, and where we are heading as members of particular cultural groups; and not least how archaeological investigations reach their scientific outcomes (Holtorf 2010). Such archaeological stories often derive their currency from drawing on the opposition of us and them, self and other. Whereas some stories project present-day conditions onto the past so that we invariably recognize ourselves

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

© 2018 John Wiley & Sons, Inc. Published 2018 by John Wiley & Sons, Inc.

DOI: 10.1002/9781119188230.saseas0034

in other periods, others paint a picture of very different and strange worlds that constitute predecessors or alternatives to present-day conditions. Either way, stories about the past easily acquire political and ideological significance in present societies when they can encourage and legitimize or discourage and delegitimize certain political goals and ideological truths.

Therefore, it is unsurprising that the history of archaeology illustrates that archaeology is anything but an innocent pastime. Prominent episodes of political contestation in the history of the discipline include the debate about human evolution and primitive human ancestors in establishing the modern scientific worldview; the national celebration of prehistoric ancestors linked to an aggressive politics of identity in emerging and developing European nation states, most prominently the racial policies and territorial claims of the National Socialist regime in Germany 1933-45 (see *HERITAGE AND NATIONALISM*); the significance of dialectically evolving prehistoric and historic societies in Marx and Engels's historical materialism at the heart of twentieth-century socialist ideologies; and claims to the remains of their ancestors by numerous indigenous groups asserting their rights in the postcolonial contemporary world.

Contemporary archaeology: Understanding the material world in present society

Archaeology's methods and approaches can also be used to learn about contemporary society itself. The material world offers knowledge and insights into human conditions irrespective of time and place (see *MATERIAL CULTURE AND SUBSTANCES AND MATERIALS*). By approaching the recent past and the present from an archaeological perspective it is possible to gain an understanding of the contemporary world that differs from the ones available through other disciplines.

The chronological scope of contemporary archaeology is a matter of definition. An important characteristic of the field that also provides temporal guidance is that it deals with a past still within the experience and memory of the living. This gives the field a floating time frame

that moves forward as time goes by. In practice, contemporary archaeology deals with the last 100 years with a special emphasis on the period from World War II to the present. This being said, contemporary archaeology should not be considered as just another period subdiscipline; it is rather an investigation into the material world, its influence on our lives, and the way it shapes our understanding of the past, the present, and the future.

Dealing with an era from which there are people with memories of their own brings about not only particular methodological possibilities but also prompts special ethical considerations for the archaeologist (see *MEMORY*). One obvious methodological advantage is that it is possible to consult people and to include their statements in the analysis. These are valuable pieces of information that facilitate a deeper understanding of the historical period concerned, but they also bring into focus the fact that memory is a complex phenomenon indeed. Individual memories are remnants of personally colored experiences from the past that unavoidably—to a larger or lesser degree—have been revised due to later events and processes. As a consequence, memories do not always accurately reflect what actually happened. Memories that are not in agreement with historical facts are however of interest nevertheless; the discrepancies make us consider why the past is remembered the way it is and people's memories thereby inject a truly human dimension into an archaeological investigation. While the contrast between recollections and the material evidence is of interest to the archaeologist it may disappoint and embarrass the informant who feels that he or she has been "proven wrong." It is therefore necessary to carefully consider how to deal with people's memories in an ethically responsible way.

Archaeological sources can be used both to complement and to contrast other kinds of sources from the recent past and present. This complementary function applies especially to aspects of the everyday life of common people or with people living at the margins of society. Archaeology can shed light on how large-scale processes and important historical events were played out, and what material impressions they made, in relation to all people in society.

Archaeological sources may also contradict other kinds of sources. A well-known example is how garbage may tell a radically different story about peoples' consumption than is reported in interviews and questionnaires (Rathje and Cullen 2001). It shows that people sometimes are truly unaware of their actual life and behavior as consumers. Another example of contradictory sources is the official Soviet claim that all fallen soldiers from World War II had been buried which has been falsified by a voluntary search movement. Using archaeological methods, members of this initiative have so far found remains of more than 450,000 soldiers left in the field (Dahlin 2012).

Besides being important as a complement and a contrast to other kinds of sources, material remains are also valuable for evoking new interest in contemporary society in aspects of the recent past and present. Things have a suggestive power to attract attention and arouse curiosity; this is especially true of objects found on excavations. The encounter with an archaeological object may start a process where memories suddenly and unexpectedly are recalled, and new questions are posed. In order to find answers it may be necessary to turn to other sources, but if it were not for the objects evoking an interest, the questions would not have been asked in the first place (Burström 2009).

Alternative research aims—beyond getting knowledge about the past

Contemporary archaeology produces other stories about the recent past and the present than those that dominate history, and also raises fundamental issues concerning humans' relation to the world around them. These issues concern both what people do with things and what things do with us. Material objects have the power not only to evoke people's memories but also to trigger thoughts and emotions of various kinds. This applies in particular to things that people recognize from their own lives and which now somehow have turned into archaeological objects.

One kind of object that attracts a lot of interest from contemporary archaeologists as well as from the general public are modern ruins, e.g., derelict

industrial sites. What seems to fascinate people is the fact that something so relatively recent is already decaying and being reclaimed by nature. In this state the material remains of modernity join other relics of the past, and suddenly the traces of the recent past seem strangely timeless. In many cases they might just as well belong to an ancient society. This insight raises the question of whether chronologically structured history is the most suitable way to investigate our relation to this composite anteriority. Things separated by time may be closely connected through other qualities and through the sensual impact they make on people. The archaeology of the recent past and the present makes us realize that the contemporary world is a mixture of material and ideas from a multitude of different periods of time; an insight that is relevant to all periods of human history (Olivier 2011).

The thoughts brought to mind by modern ruins are not restricted to the past. Experiencing how time has left its mark on the material world reminds us of the limited duration of our own existence. It generates reflections about eternal human concerns such as the passing of time, continuity and mutability, life and death (see *TIME AND TEMPORALITY*). There are, of course, no absolute or definite answers to such considerations, but that does not mean that they are futile. They are clearly an important reason why people take an interest and care about the material residues of the past.

The emotional and existential dimensions of material remains have by tradition fallen outside the field of scientific archaeology as conventionally defined. Issues concerning how things from the past in a deeper sense touch us who are alive today have been considered too personal or too subjective to be approached scientifically (see *ARCHAEOLOGICAL SCIENCES*). This means, however, to deprive archaeological remains of one of their most significant qualities, that is, their power to move people (Burström 2009). The fact that the specific content of the emotions evoked and the reflections generated will vary between different individuals is no reason to exclude these dimensions from archaeological study. On the contrary, this variability forms an important part of the answer to the question of what things do with us. Studying recent periods where living people can be observed and asked,

facilitates this kind of investigation. The insights brought about are, however, relevant to all of archaeology.

Applied archaeology

When conducted in collaboration with partners in society, archaeology has the potential to transform society. Applied archaeology actively explores and develops uses of archaeology to help solve problems for the benefit of present society (see ASSESSMENT: HERITAGE IMPACT (HIA) and HERITAGE AND SOCIETY). Jeremy Sabloff (2008, 17) discussed this approach in terms of “action archaeology” which he defined as the “involvement or engagement with the problems facing the modern world through archaeology.”

Although some archaeologists have attempted to construe general laws of human behavior or social evolution that could inform future decision-making, the results reached thus far have not been convincing. But other archaeological knowledge has various practical applications in the present (Downum and Price 1999). Among others, studies of ancient irrigation systems inspired agricultural techniques in the present, empirically observed patterns of contemporary waste disposal informed innovative waste management, and long-term paleoenvironmental studies contribute to predicting environmental trends in the future more reliably.

The usefulness of archaeology does, however, not exclusively lie in the accuracy of the insights it provides about the past. Other uses of archaeology draw on its potential, for example, to develop communities and their regions, stimulate long-term historical thinking, engage patients in therapeutic practices, inspire many different audiences, and occasionally promote particular morals. In the future, archaeology may increasingly be applied to promote democratization, empowerment, and integration (Nakamura 2012) or to stimulate existential reflections across generations and communities. All such applications transcend the traditional scope of archaeology and are not commonly taught to students in archaeology (see AUTHORIZED HERITAGE DISCOURSE).

The potential new benefits to society are large and justify preparing the next generation of

archaeologists to explore this potential further (Sabloff 2008). Future archaeologists, therefore, will need to be able not only to relate their own professional expertise to larger societal challenges but also, and in particular, to understand the necessity to collaborate in joint projects with professionals in other disciplines, especially among the social sciences, to address these challenges critically.

Conclusion

Archaeology is not only the disinterested study of the human past and its remains but also a way of making a positive impact on present society in a number of other ways. As we have suggested, archaeology tells a variety of powerful stories about past and present and offers suggestive metaphors to contemporary society, archaeological methods and approaches can be applied to learn more about contemporary society and to trigger in people existential thoughts and emotions, and archaeological expertise can be applied to help solve challenges in contemporary society. It is important for future generations of archaeologists to be aware of these dimensions and to explore and apply them critically in professional practice.

Assemblage

OLIVER J. T. HARRIS
University of Leicester, UK

Assemblages offer archaeologists new ways of conceptualizing the past for everything, from the materials they encounter to the communities they study. Rather than treating objects, people, or sites as bounded entities, thinking about assemblages requires archaeologists to focus on how these things emerge from the relationships that constitute them and how this emergent reality allows them to operate in the world. It is perhaps the most prominent new materialist (see NEW MATERIALISMS) idea at play in archaeology today.

Archaeologists are of course very familiar with the term *assemblage*, generally applying it to a set of artifacts, from a site or a region—an assemblage of flints or pottery shards, for example. The term, as it is defined in assemblage theory, is related to this, in that it refers to a gathering of different elements, but goes far beyond its traditional meaning to challenge how we conceptualize the world around us in both the past and the present. Archaeological examples will be set out below, but let us start with a familiar, everyday example. Consider your local library. We can treat it as an assemblage by thinking about how it is made up of all sorts of different elements: the books, of course, and the shelves on which they sit, but also the coffee shop on the ground floor, the staff who work there, the scholars who study there, and so on. Assemblages, however, are more than just the physical materials that constitute them; they include the rules and laws that operate there, in this case the fact you have to borrow the books rather than buy them, the signs that tell you to be silent, and the behaviors that ensue. “The library” then emerges out of all the relationships that exist between these different elements. Assemblages also have emergent properties. This means both that they are more than the sum of their parts (if you take away a single book, the building is still a library) and that they can act as a collective,

as when “the library” wants to recall your book. Equally importantly, assemblages are not static. Think of the way in which books are added to the library or leave it, staff members join or quit, students register or graduate, walls are repainted, and so on. Assemblages are thus always caught up in a process of what philosophers call *becoming*. Finally, assemblages are also multiscalar. Each of the books in the library is in itself an assemblage, one which emerges through the relationships between paper, ink, publishing companies, the thoughts and ideas of the author, and, from time to time, the interpretations of the reader as well. Even the library is one part of a larger assemblage such as a university, where it plays its role as one of the components of a wider collective.

The original idea of assemblage in this sense comes from the work of Gilles Deleuze and Félix Guattari and what they termed an *agencement*, which translates as “arrangement” or “assemblage.” Deleuze and Guattari (2004) used this idea as part of their much wider rethinking of philosophy, away from binary dualisms and static notions of being and identity toward more heterogeneous and multiple ideas of becoming. The concept of assemblage then gained popularity through the work of thinkers like Jane Bennett and Manuel DeLanda, both of whom are now widely read and cited by archaeologists. Bennett draws in the concept of assemblage to think about modern contexts. For example she examines how an electricity blackout in the United States in 2003 was caused by a whole range of interlinked factors, including “coal, sweat, electromagnetic fields, computer programs, electron streams, profit motives, heat, lifestyles, nuclear power, plastic, fantasies of mastery, static, legislation, water, economic theory, wire and wood” (Bennett 2010, 25). Tracing the reasons for the blackout, she finds that it emerged not simply from something like “mechanical failure” or “human error,” but from an ensemble of factors ranging from the economic processes that led power plants to be understaffed through a brush fire in Ohio to increased consumer demand, to the flow of electrons, and to the deficit of reactive over active power. This

event, which affected a huge swathe of a country and thousands of people, cannot be understood unless we look at the whole assemblage.

DeLanda's (2002; 2006) ideas are perhaps even more critical. Drawing on a long engagement with the work of Deleuze, DeLanda has examined how we can use assemblages to rethink geological processes, climate, science, and long-term histories. This points to a critical element of assemblages: they embrace both the side of archaeology we have traditionally thought of as humanistic (beliefs, meaning, identity) and more scientific approaches, which attend to the material elements of the world. In an assemblage there is no hard-and-fast distinction between these two, because assemblages are based on what DeLanda (2002) calls a "flat ontology." Most archaeology, whether from a processual or postprocessual perspective, has operated within a dualist ontology where cultural and social elements are treated as opposed to and different from nature and the environment. Different sides of this dualism have been privileged by different theoretical schools, but the division has remained in place. In contrast, assemblage theory argues that we need to start from a level playing field; there may be variation in scale, but that does not mean that certain things operate under one set of rules and other things under another. This also means that assemblage theory is nonanthropocentric, in other words is not centered around human beings. Instead people, who are themselves assemblages, take their place as one element among many others. So Bennett's analysis of the blackout does not privilege the role that human beings play any more than our library example above stressed the role of librarians and borrowers over that of books and shelves. These elements have made the concept of assemblages attractive across a range of disciplines, from anthropology and philosophy to politics and geography.

Assemblages, both in their original Deleuzian form and in the version developed by Bennett and DeLanda, celebrate what Bennett (2010) calls the "vibrancy" of matter, or what Deleuze and Guattari (2004, 454) call "a life proper to matter." Rather than treating the material stuff of the world as stable and static, these approaches examine instead how matter can be thought of as "alive" in one sense. This draws both on scientific concepts of how matter, despite its seemingly

solidity, is constantly vibrating and on the awareness that anything material will slowly erode away over time. Similarly, DeLanda urges us to draw on assemblages so as to think about what he calls the morphogenetic capacities of matter—that is, the way matter has its own processes, tendencies, and modes of acting in the world, rather than being at the mercy of human beings. Clay responds to certain kinds of engagement, stone to others. Thus, when we think about design, we have to think about how materials bring their own properties to the table and how specific kinds of relations between people and things can draw out new capacities without either person or material being the primary author.

Currently the concept of assemblage is being deployed in a series of different ways by archaeologists, its applicability at multiple scales meaning that it can be used to engage with a variety of archaeological questions. For example, Chantal Conneller (2011) has examined how we can offer a challenge to traditional questions of the *chaîne opératoire*—the sequence of actions that are understood as producing artifacts—by looking instead at the complex relations inherent in assemblages. Rather than following a series of "human" decisions about what to do in order to produce a particular form of artifact, Conneller traces the way in which people and the particular affordances offered by materials interacted to produce specific objects in the Upper Palaeolithic and Mesolithic of Europe. She shows how sometimes these affordances were located within the properties of the materials and sometimes in the relationships the materials had with other elements of the world, including the animals they were on occasions derived from. In a very different context, John L. Creese (2013) has described Iroquoian villages as emerging from assemblages that bound together people, houses, and forms of ritual practice in new ways. In a similar fashion, the present author has argued that whole communities of the past can be reimagined if we move away from seeing them as simply human gatherings (Harris 2014). If we think of them instead as assemblages of people, places, animals, materials, and even landscapes, then very different understandings of how these communities were formed and sustained can be developed. Finally it is worth identifying perhaps the most ambitious ways in which assemblage theory is being employed. Both

Gavin Lucas (2012) and Chris Fowler (2013) have used ideas rooted in assemblage theory to try and rethink the very nature of archaeological practice and archaeological research. Lucas, for example, argues that thinking of the material that archaeologists recover as the residue of older assemblages allows us to better understand the nature of archaeological practice, especially when we combine this thinking with an understanding of how this practice constructs new assemblages in the form of an archive. In parallel to this, Fowler examines how archaeologists themselves become incorporated in the ongoing assemblages of past artifacts and how archaeological work allows these materials in turn to be gathered into our narratives of the past in the present. For all these authors, archaeological science is one of the means by which we can attend to past assemblages and access the history of the relationships from which they emerged.

Archaeologists are therefore pursuing assemblage theory in a number of directions, from the interpretation of specific past contexts to embracing what it is that archaeologists and archaeological scientists do in the present. This research is in its early days, however, and a number of developing lines of enquiry can be imagined. What difference might assemblages make to our methodologies? How can its emphasis on a flat ontology be connected to how we practice archaeological science? How might we approach the relations between different material elements at a specific site and use visualization technologies to reconstruct assemblages in new ways? How can we use the multiscalar nature of assemblage theory to explore particular periods

in detail, working from the smallest scale of specific artifacts and contexts to the largest scales of entire periods and millennia? Many of these questions are being pursued in ongoing research projects, and more will surely follow.

Behavioral Archaeology

KACY L. HOLLENBACK

Southern Methodist University, USA

The centrality of “things” in everyday human life is widely recognized in archaeology, anthropology, and other disciplines. Modern material culture studies (see *ARCHAEOLOGY AND THE PRESENT*), the sociology, history, and archaeologies of technology (see *ARCHAEOLOGIES OF TECHNOLOGY*), and concepts such as materiality (see *MATERIAL AGENCY*), entanglement (see *MATERIAL ENTANGLEMENT*), and the new materialism (see *NEW MATERIALISMS*) are only a few examples. The diversity of methodological and theoretical perspectives related to the study of artifacts is robust and encouraging. For over 40 years, behavioral archaeology has approached social and behavioral science with a focus on artifacts, recognizing the importance of things in every aspect of human life (Schiffer and Hollenback 2010; Skibo and Schiffer 2008). Its practitioners have long argued that with its focus on material culture (see *MATERIAL CULTURE*), archaeology should be at the forefront of fields studying behavioral and technological change.

Following a theoretical outgrowth of the New Archaeology of the 1960s and increased concern with archaeological metaphysics and the philosophy of science, behavioral archaeology arose out of a need for a systematic, explicit, empirical framework to strengthen knowledge and inferences (see *KNOWLEDGE AND INFERENCE*) in the reconstruction and interpretation (see *INTERPRETATION*) of past human behavior. The approach was developed by William L. Rathje, J. Jefferson Reid, and Michael Brian Schiffer (Schiffer 1995, 1–24) at the University of Arizona in the 1970s and continued in the work of their students and others (Skibo, Walker, and Nielsen 1995; Walker and Skibo 2015). Currently, there is no uniform approach in behavioral archaeology. Instead, its practitioners are linked by a

reliance on the shared use of related methods, concepts, and theories in the study of socio-cultural phenomena. Unlike other conceptual paradigms, behavioral archaeology views human behavior as human–object interactions, privileging an artifact-oriented epistemology of the world to examine behavioral patterns, continuities, and changes in all times and all places. The framework is unique in that it defines archaeology more broadly than traditional views and is quite rigorous in its approach. It is a social science with “four strategies” that takes as its subject matter the interactions of people and things in the past *and* in the present (Schiffer 1995, 67–73; Skibo et al. 1995, 15–21). These strategies capture the diverse array of topics behavioral archaeology has focused on since the 1970s. Earlier studies focused on archaeological inference and evidence, formation processes, and the development of experimental laws through experiment and ethnoarchaeology. More recent research has turned to social questions of technological change (Schiffer 2011), communication (Schiffer and Miller 1999), ritual, landscapes, social performance, and power (Schiffer and Hollenback 2010; Skibo et al. 1995; Walker and Skibo 2015).

		Material culture	
		Past	Present
Human behavior	Past	1	2
	Present	3	4

Strategy 1 encompasses the traditional practices of prehistoric and historical archaeology, as well as studies in the history of technology. Its goal is a more rigorous interpretation of archaeological data with the important recognition of a difference between the archaeological record (see *ARCHAEOLOGICAL RECORD*; archaeological context) that we engage with and study in the present to make inferences about and reconstruct past living social systems (systemic context; Schiffer 1995, 25–34; Schiffer and Hollenback 2010, 22–25). Archaeological phenomena (i.e., artifacts, features, sites, and anthropogenic sediments) are outputs from active cultural systems, but subject

(see DISASTER ARCHAEOLOGY; Walker and Skibo 2015, 205–219).

Strategy 4 also can result in applied outcomes. It studies current human–artifact interactions to understand larger patterns of contemporary human behavior. Others would recognize this strategy as modern material culture studies or archaeology and the present. The earliest behavioral studies of this sort began in the 1970s as William Rathje’s Garbage Project (Rathje and Murphy 2001; Skibo et al. 1995, 36–43). This program studied waste disposal behaviors, as well as formation processes in landfills, to debunk myths about “trash.” Its findings are valuable for waste management and recycling policy. More recent modern behavioral research examines phenomena such as art (Walker and Skibo, 97–110) and significant sociopolitical features such as the United States–Mexico border wall (Walker and Skibo 2015, 187–204).

Currently, modern behavioral archaeology has embraced a wide variety of research. This body varies in the types of questions and research goals adopted, but is unified by concepts and approaches arising from the four strategies. In addition, it is important to recognize that many approaches to archaeology today, which are not explicitly behavioral, utilize these concepts. For example, there is now a universal recognition of the importance of formation processes in constructing inferences about the past. Future behavioral research will likely continue to build on models of strong archaeological inference, but will embrace more applied endeavors, such as those illustrated in strategies 3 and 4.

Bodies and Embodiment

LINDSEY BÜSTER

University of Bradford, UK

Introduction

Theories of the body and theories of embodiment (see EMBODIMENT) describe a series of perspectives that explore how humans perceive and experience the world through their physical and social bodies. Embodiment is distinct from concepts of “the body,” in that the former is a solely biological/material entity, while “embodiment” is a theoretical and methodological framework which acknowledges the socially constructed nature of the body and the ways in which it interacts with the world. The concept of embodiment is based on two fundamental principles: first, rejection that cognition (the mind) exists independently of the body (as posited by classical philosophers such as Plato and given preeminence during “the Enlightenment”); and second, rejection of the assumption that the biological, physical, and bounded body exists as the foundation for the interpretation of experience, separate from other aspects of the material and immaterial world (animals, plants, places, things). Arising from trends in sociology (Featherstone, Hepworth, and Turner 1991) and anthropology (Joyce 2005), in response to structuralist theories which divide the world into dualistic distinctions between, for example, mind and body, subject and object, perception and practice, theories of embodiment question our understandings of the concept of “the body” and seek to understand how physical and social bodies are constituted and reconstituted via interactions with other living and nonliving things.

Central to theories of embodiment is the acknowledgment that mind and body do not represent different facets of a person, and that ontological understandings of the world are constructed and mediated through the “practical ontology” of corporeal experience. In other

words, “while culture clearly bounds and directs individual understanding of cultural meaning, the actual process of meaning making and identity construction are built upon individual experiences, emotions, and interpretations” (Dornan-Fish 2012, 284). Robb and Harris (2013, 17) have captured this cocreative nature of body and world—this “dynamic feedback loop” (Dornan-Fish 2012, 285)—through their discussion of “body worlds.” Thus, theories of embodiment allow for conceptualization of the body as cultural and historical, biological and material, and acting as the medium through which individuals perceive, experience, and engage with the world, its objects, and places.

People, things, and places: archaeologies of embodiment

Phenomenological approaches in archaeology have sought to “people the past” and to understand past worlds from the human perspective, with a particular focus on the emotional and sensory aspects of places and things. It has become apparent, however, that we need to question what *kind* of people we were peopling the past with. Drawing on the *habitus* of practice theory, together with structuration theory, approaches to the body and theories of embodiment view particular ontological understandings of the world as historically and contextually specific: a “phenomenology of perception” (Csordas 1990, 33). As such, no one universal concept of corporeal experience can be assumed across time or space, including between people in the same society, or by the same person in different social contexts.

Bodies, identity, and power

If ontological understandings of the world are historically and contextually specific, then so are the many aspects that make up social identity. As such, social identities are relational, in that they are not predetermined but formulated in relation to those around us, and are, at the

DOI: 10.1002/9781119188230.saseas0066

same time, mediated through the specificities of our physical bodies. Critics argue that too much focus on the subject-specific body risks neglecting overarching social power structures in which these bodies (these individuals) operate. Others argue, however, that individual choice and collective choice are not mutually exclusive categories. Indeed, Dornan-Fish (2012, 282) suggests that it is impossible to discuss concepts such as power without also acknowledging processes of internalization within our own bodies, since “it is in the process of individual meaning-making ... that shared cultural symbols gain or lose their power to constrain or enable social action”; that is, individuals are *parts* of social structures, not external to them. As such, theories of embodiment provide more nuanced understandings of the way in which power dynamics in society operate, in contrast to homogenizing terms such as “resistance,” which have the potential to misrepresent the intentions, experiences, and self-identification of both “oppressed” and “oppressor” (Dornan-Fish 2012, 291–2).

One of the first areas of archaeology in which theories of embodiment were explored were studies of gender and sexuality, particularly within feminist archaeology (see *GENDER AND SEXUALITY*), in which power and inequality are central themes. Butler (1993), a major influence on this theoretical turn, argued that terms such as “male” and “female” are not biologically absolute, but rather performed through a series of regulated practices. These practices in turn create idealized gender types and reinforce them as naturalized states of being. Take, for example, modern public lavatories and the strictly binary gender types that they reinforce, or studies that have shown the different ways in which people interact with “male” and “female” infants, engendering their corporeal experiences from an early age. Dissatisfied with assumptions that a stable biologically sexed body necessarily represents a uniform foundation for socially constructed gender, as portrayed, for example, through clothing and ornamentation, archaeologists have sought to understand the ways in which the corporeal experiences of different types of body created (and recreated) variously gendered ways of experiencing and understanding the world (and vice versa). In this dialectical relationship, these identities need not be static, since their

performative recreation leaves them inherently mutable and open to change. Such considerations do not limit themselves to gender, and include other facets of social identity such as age, class, and clan affiliation, which are simultaneously operating on and within the body, and in its representations (Joyce 2005). Before we can examine these aspects of a person’s social identity, however, we need to establish what we mean by “person.”

Embodiment and personhood

Within a liberal humanist framework, modern western societies place great emphasis on the individual and indivisible, bounded nature of the human body—a concept that has arisen from, and is supported by, our capitalist and consumerist economy. In this perspective, people are individuals and individuals are people. In our society, individual agency (the capacity to do things) is fundamental to concepts of freedom, empowerment, and moral responsibility, and, as such, there has been a rise to incorporate aspects of “the individual” and “individual agency” into past narratives.

The perspective of “the individual,” or indeed any universal concept of corporeal experience, should not, however, be taken for granted as an a priori state of being, and different “modes of personhood” are frequently recorded in non-western societies across the globe (cf. Fowler 2004) (see *PERSONHOOD AND OBJECTHOOD*). One mode of personhood often cited in contrast to modern, western ways of experiencing the world is “dividual personhood,” in which bodies are understood not as strictly bounded physical entities, but comprising a series of parts (material and immaterial), which can be separated out and exchanged (partible persons) or influenced and reconfigured by flows of substances (permeable persons) (Fowler 2004, 7–9). These different ways of experiencing the world can be found, for example, in Melanesia and India respectively, though shamans or members of any totemic society might also be considered to possess more fluid ways of understanding the construct of the physical human body. Even today, in some forms of Christianity, “possession” by evil spirits or being overcome by the power of God indicates

a perception of the body as permeable to other types of “person” and/or “flows” of energy (cf. Csordas 1990).

Indeed, drawing firm distinctions between “individual” and “dividual” persons represents something of a falsehood, since in most societies, a person’s understanding of themselves fluctuates between and within these two extremes, depending on context. Though the concept of “the individual” as a physically bounded body is often the dominant mode of personhood experienced in the modern West, there remain certain contexts in which dividual aspects of our personhood are elevated: in our attitudes towards the dead and our processing of grief, for example (cf. Crossland 2010). Objects associated with the dead—particularly those that have come into direct contact with the body (such as clothes)—are frequently treated as containing some lasting “essence” of that person, which makes their reuse or disposal particularly problematic. Furthermore, the language used to describe bereavement, such as people being “filled with grief,” suggests an underlying concept of the body as a vessel, through which our emotions “flow.” In addition, the modern western premise that individuality is something unique to humans is called into question when we consider the social status given to nonhuman agents such as pets. And what implications do concepts of embodiment and personhood have, for example, in our consideration of “post-humans” and other forms of artificial intelligence—can we, do we, and will we confer the status of “individual” to these bodies?

Embodiment and materiality

Archaeological studies of embodiment necessarily draw on theories of materiality, since it is predominantly through material remains (artifacts, for example) that we study the *people* of the past. Materiality describes the material and immaterial affordances (or bodily experiences) of an object, place, or thing; the hard, cold, and durable qualities of stone versus the soft, warm, and impermanent characteristics of wood, for example. We have discussed the central role that material and immaterial things play in structuring (and creating) our bodily experiences

and understandings of the world, and materiality plays a vital role in this. The materialities inherent in wood and stone have, for example, been variously employed as a metaphor for the human body (living and dead respectively), while bread and wine in the Christian Eucharist serve as metaphors for the body and blood of Christ (and also represent a modern, western example of dividual personhood).

In societies that tend towards dividual modes of personhood, aspects of a person’s body can be distributed in a range of material and immaterial things. As such, humans represent just one part of an assemblage or “entanglement” of plants, animals, objects, and places. Things and places that we may assume to be passive backdrops to human existence (landscapes and architecture, for example; see *INHABITED LANDSCAPES*) thus become active agents in the creation, negotiation, and maintenance of ontological understandings of the world.

Embodiment and agency

In an attempt to overcome modern divisions between subject and object, anthropologists developed “actor network theory” (see *ASSEMBLAGE*; *MATERIAL AGENCY*; and *MATERIAL ENTANGLEMENT*), which focused on the fluid relationship between humans and nonhumans. Others went further still, imagining humans and nonhumans as “entangled hybrids,” “socio-technical assemblages,” or “socio-technical collectivities,” in an attempt to move away from the mind–body dichotomy (Crossland 2010, 394). In these approaches, neither human nor object are afforded any particular “agency” over one another (*contra* Gell), as this is viewed as overly subject-centered and humanistic.

Here we see a theoretical tension between the call to consider the agency of objects—in acknowledgment of the central role our material surroundings play in the constitution of our embodied selves—and the effective loss of agency in entirely relational and symmetrically distributed concepts of this embodied self (cf. Crossland 2010, 394). Indeed, critics of actor network theory see it (in its most reduced form) as positioned in direct conflict with theories of embodiment, since it erases the performative

aspects inherent in the constitution of our bodies. In denying agency to people in the past (particularly those with more “dividual” modes of personhood), they are left unable to distinguish their minds and bodies reflexively from non-human things, other persons, or the societal structures that “bind” them, nor to pursue any goals independently of society at large (cf. Crossland 2010, 283; Dornan-Fish 2012, 284). Indeed, “intentionality” lies at the heart of theories of embodiment, and “all archaeological interpretation is to some extent about understanding past intentions” (Dornan-Fish 2012, 287). It is arguably the under-theorizing of the complex intentions and motives of embodied persons in the past that leads to oversimplified readings of the archaeological record, and we walk a “fine line between postmodern conceptualizations of society as nothing more than a jumble of unrelated subjects, and cultural constructivist conceptualizations of individuals as nothing more than a sum of their collection of identities” (Dornan-Fish 2012, 294). Diminishing the possibility for agency and intentionality has implications not only for the past but also for the future, effectively writing theories of embodiment out of discussions surrounding post-humans and artificial intelligence; discussions that are likely to become more central to our understandings of what it is to be “human,” as the distinction between “biological” and “technological” bodies becomes increasingly blurred.

Post-script: embodiment and the dead

Though they form the basis of our interpretations about the past, the dead (as dead people and as dead bodies, rather than as silos of information on the living) are often overlooked in discussions of embodied experience in archaeology, emphasizing our modern adherence to the mind-body dichotomy (cf. Crossland 2010, 402). It is possible, however, that death simply signaled (and continues to signal) a “transformation of embodiment” (Crossland 2010) rather than its cessation, and that our failure to ascribe embodiment to dead bodies reflects our modern philosophical positioning. Indeed, Crossland’s (2010, 402–405) discussion of forensic archaeology demonstrates that the language commonly used in relation to

dead bodies (particularly in mainstream media) demonstrates a tension between the dead as representing “matter without mind” (Crossland 2010, 402), and yet possessing continued agency. Considering embodiment in the past therefore prompts us to reflect on our own ontological positions (and contradictions), and the ways in which we “use” and interact with the dead (including the long dead) in contemporary society.

Archaeological bodies and embodied archaeologies

Theories of the body and of embodiment are relevant not only for how we understand people in the past, but also for how we understand ourselves and others today. Indeed, they are critical to our understanding of the underpinnings of archaeology as a discipline. Archaeologists have increasingly become aware of the andro- and ethnocentric biases inherent in interpretation. Theories of the body and of embodiment take this a step further, in their recognition of the historically and contextually situated embodied self. As such, they force us to acknowledge archaeology as a socially mediated form of constructed knowledge and practice, and what this might mean for our understandings of the past. They also force us to reevaluate the structural *status quo* of contemporary society, and highlight the role of the archaeologist in maintaining or challenging the embodied “norms” we take for granted. By helping us to step a little closer to those whose lives we glimpse through their relationships with the material traces of the past, we also create more nuanced understandings of our own place in the world.

Creativity

ANDREW COCHRANE

Cardiff University, UK

Humans have always been creative and everyone is creative. To imagine otherwise suggests that some people can do things, while others cannot. Archaeologists have not always been so generous in their accounts. For instance, humans have historically only been regarded as creative since c. 40,000 years ago, with the advent of a “creative explosion.” Such eruptions are often depicted as first occurring in what is now termed Europe (mostly in Spain, France, and Germany first), with the arrival of decorated caves, sculpture, ornamentation, and musical instruments. For example, we have the so-called *Lion Man* mammoth ivory sculpture, Germany, at c. 40,000 years ago, and the earliest black drawings and charcoal marks in Chauvet Cave, France, around 37,000 to 33,500 years ago (Jones and Cochrane 2018). We have evidence for some of these elements occurring in Africa around 75,000 years ago, at Blombos Cave. Here, numerous engraved red ochre pieces were discovered, and at least 49 perforated shell beads, with marking from use and the application of ochre. By 10,000 years ago, traditional narratives report that humans started to think symbolically, with the development of status, value, power, and metaphor. These are seen as complementing the rise of sedentism with domestication, soon followed by social stratification, inequality, cities, and metallurgy.

Renfrew (2008) creates the notion of a “sapient paradox” while thinking about the materials humans modify. Renfrew questions why humans from at least 150,000 years ago, who share the same potentialities as us (they are anatomically modern and sapient), do not create the kinds of decorative assemblages that we see around 40,000 years ago (Blombos being an exception to the rule). He further puzzles why it is only around 10,000 years ago that humans get their

act together in a creative fashion, and started to build the world (Renfrew 2008, 2043); that is the paradox. Improved climatic conditions from the late Ice Age onwards helped, but do not fully address this quandary. The short answer is that there is no paradox. Gamble and colleagues argue that archaeologists are stuck in a *what you see is what there was* approach to the past (2014, 152). Such perspectives only afford past humans attributes that can be inferred from the materials found (e.g., chipped stone and butchered animal bone). Gamble and colleagues (2014) suggest that we must consider elements that might not survive in the ground, but are still key to being human. These can include: friendship, laughter, emotions, dance, language, music, and of course creative thoughts. The challenge for the archaeological future is for such considerations to complement more material based approaches.

Another facet of traditional accounts relates to replication of technology as stasis. Early humans are depicted as lacking originality and change is the exception. Copying and repetition of form is, however, not mere replication via template; it is a complex and ongoing alignment of things in the world (Hallam and Ingold 2007). It takes work, and therefore even the maintenance of long-term traditions that are similar are not inertia, but are active creativity (e.g., Acheulean and Levallois techniques). Creativity is not *just* about change—there is no reason why the 100,000th version should be any less creative than the first—as all are momentary engagements with the world. There is also no guarantee that the 100,000th version will be like the first, while it is being worked with. Replication of existing forms leads to variations in the situated processes that might not be visible archaeologically (e.g., within a group of people). A legacy of the Renaissance is that the creative act is about discontinuity rather than an ongoing process. Historically, archaeology has been retrospective and primarily focused on the *created* (what was made); more recently it looks towards the *creating* (the process of making) (e.g., Jones and Cochrane 2018). Creativity is an ongoing journey of repetition and

repertoire building; definitions and approaches influence how we think about the past.

How we recognize creativity in archaeology today is framed by the development of the concept. It has had a long and deep history in the West, with origins in the Judeo-Christian traditions of Genesis. Medieval beliefs fostered the notion that God created things from nothing; humans merely juxtaposed existing things in new ways. In the thirteenth century, the term *create* was predominantly in the past tense (was created). By the fifteenth century, we witness the occurrence of the present principle *creating* (what is being created). The belief that things are made from nothing (i.e., they are original) persists. Human agency does not really become associated with acts of creation until the sixteenth and seventeenth centuries; it is, however, often seen as suspect when it does occur. From the eighteenth century onwards, many seem to be more confident in the human ability to create, and the word *creativity* first appears in English texts in the mid-nineteenth century. This is also when we have the late Romantic elevation of the artist as an individual genius, and beliefs in authenticity, as an anathema to mass reproduction. Through the twentieth century, creativity became something that anyone could claim (buy) or aspire to, via processes of democratic consumerism (see detailed discussions in Pope 2005; Hallam and Ingold 2007; Svašek 2016). A recurring theme running through this century was that to *copy* was not to *create*. Such thoughts have cast a long shadow over archaeological explanations.

Today, the idea of the Lone Creator (the genius, the talent) existing in the West is no longer dominant. Instead, creativity is viewed as existing within networks that foster a diversity of perspectives (the Internet has helped here). Creativity is no longer the result of the void, but rather an assembly of preexisting elements, often in different configurations (see also ASSEMBLAGE). Conversely, creativity is still linked to innovation and newness; creation from a void. Not all like the word *creativity*, some think it a lazy debasement that lowers all to a common denominator. Yet, we live in a world that wants more and more creativity (irrespective of its origins), and many are strongly encouraged to be creative in the workplace (Liep 2001, 5). One of the driving factors of creativity in contemporary commercial sectors is

leadership as mediator-based creativity; here the leader acts as moderator. This can work via four mechanisms: motivation, affect, cognition, and context. This can lead to an empowerment of the group and the forming of new creative relations. The early Neolithic stone known as Grand Menhir Brisé, Locmariaquer, France (c. 4,700 BC), wonderfully demonstrates such mediations. This megalith is currently broken into four pieces; when whole it was c. 20 m long and weighed over 300 tonnes. It was quarried from about 4 km away from its current location. The efforts involved in finding the material, removing it from the ground, shaping it, moving it vast distances across terrain, and finally erecting it (probably next to 18 other standing stones), were epic. This was only possible by collaboration and creative leadership; the ability to influence and affect others in the world (Richards 2013); the power of charisma. That it fell and smashed also highlights the risks involved in mediator-based creativity.

The twenty-first century has already witnessed provocative changes, in part generated by economic and political problems, and fueled in some instances by weak leadership (Shalley et al. 2015, 2). Within such environments, companies and industries that remain static (e.g., they do not create new things) are often seen as being in a state of dying. To resolve such issues, many companies name creativity as a priority and solution (Shalley et al. 2015). This makes sense, as huge dividends can be accumulated by the creative arts. The importance of a new idea is key to creativity (as idea generation) and innovation (as implementation). Again, these contemporary approaches to creativity influence how we depict the past. By acknowledging how we think today, we can move beyond progression and innovation as forms of social evolution, resulting in explosions and revolutions in deep history (Gamble et al. 2014). Creativity in archaeology is no longer just the prerogative of the divine or humans, it can also work with assemblages of things, that collaborate or disrupt (Olsen et al. 2012).

Archaeology can offer important deep time perspectives that are less available to other disciplines; we can examine change over long durations, and we are able to examine how creativity relates to a spectrum of factors. Some people are happy to take risks and violate paradigms; this mostly works best after one

has first learned the rules. Skilled practitioners often excel by being able to improvise and adapt to changing circumstances (Hallam and Ingold 2007, 12). An archaeological example of such processes can be seen in the decorated Neolithic macehead from the Knowth Site 1 passage tomb, Ireland. Recent applications of reflectance transformation imaging (RTI) on the flint macehead has helped reveal how it was worked (Jones and Díaz-Guardamino 2018). The macehead (790 mm long) is decorated with spirals, lozenges, and arcs. On each side of the macehead there is a single spiral; on one side there is an arc that inverts at the ends, and around the central handle-hole there are lines, one of which radiates off into a spiral. The ends of the macehead have close fitting lozenge motifs that are carved in relief; the spiral decorations on the front and sides of the macehead are executed in shallow relief. This is an unusual technique among the known corpus of decorated things from Neolithic Ireland and the United Kingdom. The white flint is much harder than the orange, and these texture differences affected the Neolithic carver. On one of the faces of the macehead, the spiral decoration passes through a region of hardened white flint, thereby deflecting the carver's hand, disrupting attempts at symmetry and perfection. The flint does not collaborate passively. Modern technology allows us to see new things, and it highlights that at any given moment, things can go astray. Creativity works via process, involves risks and some certainties, and is always in a historical moment.

Destruction is also a creative practice. For instance, the island of later Neolithic and early Bronze Age Crete is a world popularly characterized by athletic men, bare-chested women, and snake reverence. It has also produced some of the most iconic sculptures in the world, among them the so-called "Snake Goddess" figurines from the Palace of Knossos (c. 1900–1100 BC). Excavating in 1903, Sir Arthur Evans and his team, discovered two cists within the floor of the palace; within them (known as East Temple Repository and West Temple Repository) was found fragmented faience figurines. Here, we have not only deliberate breakage but also specified deposition. Two figurines present identical breakage patterns: they are both decapitated, have the left arm removed, and are broken below

the hips. They demonstrate fracture lines caused by impact from a heavy instrument or by being held in the hand and smashed into a harder surface. What we have is not only intentional mutilation, deposition, and assemblage, but also the deliberate separation of parts (see Jones and Cochrane 2018, and references within). Fragmentation might be a means by which relations between people and groups were maintained or established. Significances arrived via creative destructions and additive subtractions.

Things happen in the present. We now exist in a post-*Gathering Time* Bayesian world (see BAYESIAN STATISTICS). For years, approaches to understanding how creative things happen were hampered by ahistorical essentialist and universal narratives, that could be applied to any place at any time. Instead, Bayesian dating is now able to help us create useful models for witnessing the tempo of change in the past. Most recently it has been successfully worked through Upper Paleolithic decorated caves (see the newest set of dates above), Neolithic monuments, and Anglo-Saxon graves. Archaeologists are challenging the idea that things, particularly ones worked with by humans, were the result of predetermined ideas. Instead, in explanations we have relations of things—affected and affecting—determining overall process. Gone also is the established belief that things happened slowly over long periods of time in the deep past. The Neolithic monument named West Kennet Long Barrow, in England, highlights such shifts in perspective. For most of the twentieth century, it was explained to have a slow history, being open for some 1,000 years, with the bones that were deposited within, often being moved around the environment. The bones were old venerated ancestors and were associated with fertility; Bayesian modeling gave us a different narrative. We now have a relatively quick build monument created, with at least 36 people placed in it. This happened at a generational scale of 25 years or so, between 3,670 and 3,635 cal. BC, with the last primary deposit going in c. 3,640–3,610 cal. BC. We no longer have timeless or anonymous forebears; rather there are known, remembered, and accountable people. In terms of expression and creativity, this is a completely different story that operates in human lifetimes. High Resolution dating techniques (e.g., Bayesian modeling), strontium isotope analysis

(see MOBILITY AND STRONTIUM ISOTOPES), aDNA studies (see e.g., DNA: MITOCHONDRIAL) inter alia, are increasingly allowing us to notice specific changes and movements at different scales, for example, lifetime, generational, settlement, and environment. We can now better witness the actions we have previously speculated over as they unfold. Creative processes do work, on the ground, beyond theoretical modeling.

As we have seen, creativity is a difficult topic to pin down, because it is slippery. It is impossible to define as it has no single image of thought of its own. It subverts attempts to subordinate it to a particular model (Pope 2005, 36), via a paradoxical process of *defining creativity by creating definitions*. Ironically, archaeological writings themselves are often the greatest acts of creativity.

FURTHER READINGS

Critical Theory

MARK P. LEONE

University of Maryland, USA

Critical theory assumes two positions that are complementary and even essential to each other. One comes from the Marxist scholars who adapted economic and political analyses from Marx and Engels to late twentieth-century capitalism, particularly focusing on why many of the most exploited in a society could not see clearly the institutions that exploited them (Lukács 1971; Althusser 1971; Habermas 1984–7; Frisby 1996). Those people, classes, groups, and ethnicities often supported proxies for those who were ruining their economic lives. Such an emphasis—such a problem—often settled on studying ideology as an intellectual object. These scholars founded the Frankfurt School and critical theory.

A second and much less integrated assumption in critical theory is the notion of projection from psychoanalysis, as articulated by Freud (Žižek 2012). Some archaeological projects see the elements producing conflict in the present as being placed on the past, making the past unable to serve the present independently or scientifically, and making the past a function of those parts of society that are least able to see that capitalists satisfy their own interests (Orser 2004). The idea that the past was made to serve the interests of the currently powerful was established before Freud. It is only in the last 30 years that this idea moved into archaeology.

Critical theory produces two kinds of archaeological analyses. Most of these concentrate on economic and political factors, because that is what their authors (Orser 2004) think is most useful as they see the needs of their own society. Second, critical theorists also write archaeological presentations of groups, classes, populations, and regions whose past is a scandal to capitalism. While I use this word to catch attention, it actually has two meanings. Critical theorists make it their job to find and describe the exploited (Delle,

Mrozowski, and Paynter 2000; González-Ruibal 2008; Larkin and McGuire 2009). One device employed to do this is to describe the lives, customs, heroic attempts to escape exploitation, early deaths, and short lives of those people whom capitalism ruins in its quests for raw materials, markets, cheap labor, cheap transportation, noncompetitive conditions, unregulated business practices, and a supportive system for collecting wealth in unlimited ways and amounts. This is where critical historical archaeologists have made the greatest progress, reshaped the field and its goals, made the greatest impact in the classroom on undergraduate and graduate students, and faced the greatest difficulty with colleagues in cultural anthropology, who often prefer to see a more complex world, one less determined by economics and politics.

No one ever said that Freud and Marx set out to achieve the same thing. Only by saying that both created critical theory could anyone say that they had something in common. The element in common is dealing with living conditions now, today—which is often so difficult because there is so much exploitation on the one hand and so little understanding of where it comes from and what to do about it on the other (Žižek 2012). Freud, as we all know, dealt mostly with patients, not with society. But, no matter how much that point is stressed, we all know that the point of all public archaeology, almost universal now, is to provide an answer to the big question: Where do we come from? (Lukács 1971)? How did we come to be in the condition we find ourselves in now? Public archaeology, while frequently light on its delivery of answers to these panhuman questions, is an offshoot of Freud's understanding that the present projects itself onto the past to justify its actions and to hide its motives. Public archaeology can be used for tourist purposes, but usually is not. Its aim is to show how the past is composed, put together, made, or interpreted. We think up the past; we don't dig up the past. This was our final sentence on public excavations in Annapolis. This is the second kind of analysis produced by archaeologists writing with critical theory (Sayers 2015).

Freud's work in the hands of critical archaeologists has as its purpose putting in anyone's hands an understanding that not only is his/her past accessible and available, but there is an entire scientific field devoted entirely to achieving this very end. There are professionals to talk to who know the evidence for slavery, indenture, factory working and living conditions, eating conditions, medical conditions, early death, diseases, prisons, workhouses, famines, massacres, and torture chambers. Critical archaeologists have done all these analyses and so much more. All this work is done to tell us how we got into the conditions we are in, who is responsible, and where the other history is. Just as Freud said, the facts are friendly, so critical archaeology presents a past that unifies people with a current need for answers to the question of where the past went and, once retrieved, what it can say that is freeing. Freud actually saw dreamwork as akin to archaeological stratigraphy. He knew he was using a metaphor. In critical archaeology we are not using a metaphor. We have seen that, when people explain out loud how they and theirs came to be in their current condition, using the language of the masters, people listen and accord respect. Does this make a difference (Žižek 2012)? Yes. As people who only guessed at a past come to see both the evidence of one and how to reason with the evidence, there is a different reality that is created. Does it stop exploitation? It does for some. Is it a redemptive act against capitalism? No. However, this way of thinking about, and doing, archaeology is new, if we judge by what American archaeology looked like before the 1960s.

It might be wise, at this moment of doubt as to whether critical archaeology has or even can accomplish anything, to place our collective scientific efforts within the objectives of the origins of nineteenth-century archaeology. We know, or at least are told, two origin stories about the reasons why prehistoric archaeology was founded. One, and a minor one at that, was to achieve a history for those nations and peoples not touched by Roman expansion into northern and western Europe. Digging in the ground was to be the alternative to not being mentioned by Julius Caesar, Hadrian, or Constantine. The second and far more important origin story was to provide an entire empirically based narrative about human and cultural origins beyond those

promoted by established churches, themselves viewed as too powerful, ignorant, or corrupt to be allowed to be the keepers of anybody's genesis.

With such a point, archaeology could and did use Nicholas Steno's insights into stratigraphy to eventually build a universal chronology free from supernatural intervention, underpinning a humanity that could be understood apart from employing sin, soul, purpose, or redemption. For better or worse. This secular yet noble purpose was to be rational and has succeeded in producing archaeologies for virtually all peoples and places on the planet.

A critical archaeology fits into this idea of a secular archaeology by being socially redemptive within the Marxist tradition. Its users ask: How can society, particularly capitalist society, be reformed (Althusser 1971; Lukács 1971)? Compared to nineteenth-century archaeology's concern with secular origins, a critical archaeology informed by Freud's work uses a more locally situated voice to discover what social or political matter needs to be worked on in such a way that archaeology or material culture can provide an answer. This usually means that archaeologists ask the people we or they work with what they want to know or achieve through archaeological work. This effort is often called public archaeology; it has taken many forms over the last 30 years and has had an impact that has been neither fully evaluated nor recognized.

The common link between the bigger early goal of archaeology and critical archaeology is a concern with the conditions of the world that archaeology moves in, on the understanding that it is this world that archaeology serves. How does archaeology fix conditions now with its work? Such a statement serves a local and a universal purpose simultaneously (McGuire and Paynter 1991; Larkin and McGuire 2009).

One example will make clear how critical archaeology works—but over decades. Historical archaeologists began work on North American plantations 40 years ago. We excavated slave quarters, overseers' cabins, great houses, fields, canals and dams, sugar mills, cemeteries of slaves, biracial communities, African American houses in towns and cities, property of people who were free before US Emancipation, African religious practices, Afro-Christian sites; and we talked with descendants, other communities, and anyone

in media who could reach any of these peoples. There was a search for African customs and traditions, or for some culture carried from Africa to North America. There was a concern with the archaeology of those who freed themselves from slavery, racism, segregation, tenancy, and halfway manumission. This was the archaeological version of the American Civil Rights movement. This effort in historical archaeology was not founded to be critical archaeology, even though some critical archaeologists worked within it and used critical theory to make their contributions.

The founders of the American Civil Rights movement certainly knew the neo-Marxist ideas of post-World War II Europe that, taken together, are critical theory, yet those ideas were barely visible in plantation archaeology; but they can be. In 1982, Orlando Patterson published *Slavery and Social Death* (see Patterson 1982). Patterson is a sociologist and quotes much of the same literature used by historical archaeologists who use critical theory. He might not call himself a critical theorist, but that does not matter given his main ideas, clearly so self-reflective on our own society that they complement critical theory and carry it further than we historical archaeologists do.

Patterson (2012) has three ideas that can revolutionize plantation archaeology and African American archaeology. One is that a slave—any slave in Greece, Rome, the Caribbean, or North America—is made into the property of the slaveholder by violence, as a person having no legal rights left, no ownership of her or his children or spouse, no property, possessions, or self. The enslaved has no former name, country, cultural tradition, kin, or history. Nothing remains. Through unpredictable and wonton violence, the slave must remake himself and herself into an image provided by the master, acknowledging the master's complete control over the enslaved's body, sexuality, life, and future. The slave is to become a parasite living on, off, and for the slaveholder. This is what Patterson calls social death. This is not an idea that has penetrated plantation archaeology.

Patterson's (2012) first point goes on. Because the enslaved's kin are owned by the slaveholder far into future generations and because slavery attempts to erase everything that marks a difference between a slave's former self and the slaveholder, the slave is left empty. When this

happens legally, over many generations, only a living corpse remains. The mark of former slavery is a combination of established inferiority, racist ideas of subordination, historical ignorance, but above all an attempt to create nothingness in a person. How to put humanity back into this emptiness has hardly even occurred to us as historical archaeologists, because we have not normally seen the depth of the problem. Yet that is supposed to be the role of plantation archaeology.

Patterson's second idea is that St. Paul invented, out of the teachings of Jesus of Nazareth and the Hebrew Bible, a version of Christianity that served Roman slave society by focusing on salvation through redemption from sin as well as on punishment for violating God's laws or commandments. Pauline Christianity preserved class, property, obedience, sin for disobedience, and stability within what was, at the time, the world's largest slave society. This became the religion of the slaveholding South for blacks and whites, as both groups experienced the emotional depth of the Second Great Awakening. There was to be no rebellion on either side. Patterson's novelty is not his critique of Christianity in St. Paul's hands. His novelty is bringing to life, in the American South, a religion created for slaveholding Rome, by offering a hypothesis that the Christianity of both places was the same and served the same purpose, whether believed in by slave or slaveholder. Here is St. Paul: "Slaves, obey your earthly masters with respect and fear, and with sincerity of heart ... Obey them not only to win their favor when their eye is on you, but as slaves of Christ ... And masters, treat your slaves in the same way. Do not threaten them ..." (Ephesians 6: 5–9). Where, we might ask at this point, is the archaeology of this hypothesis?

Patterson's (2012) third point has never occurred to those of us writing about African American archaeology: what slavery does to the slaveholder; yet the question has been known for years. The violence needed by the slaveholder to make an enslaved person is constant, unpredictable, given often for no reason, and has as its purpose the utter degradation of the slave. Marcus Aurelius knew this made a demon of the slaveholder. Frederick Douglass saw this result as well. We, within critical theory, missed it. How and with what result? We have left the slaveholder alone, or to the novels of William Falkner. We

have never had a good way of understanding the toll that inflicting and rationalizing violence took on a master's personality, on the slaveholding class, or on its Christianity.

Patterson's (2012) third point continues. He points out that social parasitism is supposed to make the slave a function of the master's complete self and of his desires. But the reverse happens. The slaveholder comes to be the parasite on the slave, who provides a sense of virility, importance, accomplishment, and wealth and a supplement to the slaveholder's being. So the master is as degraded as the enslaved has to be in order for the slave to be kept a slave. How do we use these critical insights?

We use them in two ways. For the purpose of using critical theory now in historical archaeology, I offer the hypothesis that slavery in the United States and in the West never went away. It remained and was transformed, and our job as historical archaeologists is to use its archaeological traces to understand its origins and to deal with its victims. Such an approach allows us to maintain a focus on the modern descendants of North American slavery as well as to concentrate on enslaved people who are not African Americans but who still live under conditions called trafficking in persons (TIP).

The concept that links legal slavery in North America, descendants of North American slavery, and trafficking in persons is manumission. Orlando Patterson offers the idea that Roman slaveholders saw that their greatest tool to control a slave was the slave's desire for freedom, independence, worth, and dignity, all to be achieved through manumission. Because manumission worked only insofar as it was a promise and a possibility, it could never be fully realized, but was always, even when achieved, conditional. Manumission, to work, could never be complete, otherwise the slave could not be controlled any longer. Manumission had to be partly real, partly lie. With the promise of manumission the slave could be seen to work very hard for it. But, even when manumission was achieved, the slave was still stigmatized by his/her former status. So slavery never fully went away. In North America this stigma was retained through Jim Crow racism and its laws.

It is this conceptualization of manumission that leads us to understand the need for

an American Civil Rights movement and our involvement in plantation or African American historical archaeology, the importance of many different Afro-Christian religions and churches, and the extraordinary resilience of racial inequality in North America. In this sense, because manumission was a half-promise, we can understand that the descendants of North American legal slavery do not want their unique history to be compared to slavery in ancient Greece and Rome, where slavery really is gone. With these arguments, historical archaeologists have a critical reason for not abandoning African American historical archaeology. The critical reason is: African American slavery never fully ended, but continued and continues through racist efforts to keep some citizens subordinate.

Once we have an intellectual way to see continuity in slavery over time, from Greece, Rome, the Caribbean, and North America, because the conditions and the definitions promoting it continue, we can see and add living slavery.

Such current slavery is called trafficking in human persons and is well documented by the US State Department (<https://www.state.gov/documents/organization/258876.pdf>); it, too, has recently been analyzed by Patterson (2012). The State Department report counts over 35 million slaves in the world today, most of them coming from the United States, Mexico, and the Philippines. The report counts 60,000 in the United States in 2016. The point here is that a critical approach asks about political and economic conditions in the past and how these allow us to see how peoples today came to be in the condition they find themselves in. Such an approach allows us to see that slavery is not dead, may never have been fully eliminated in nineteenth-century North America, and exists again as trafficking in persons.

For example, the 13th Amendment, though meant to emancipate, did not do away with slavery in our society. The amendment disallows involuntary servitude "except as a punishment for crime." Recognizing that the high incarceration rates in the United States are an aspect of a slave-permitting society is important to addressing that problem in its modern form. The race-based justification for slavery on the plantation did not end in the nineteenth century. Racial disparities in the criminal justice system

carry prejudices and inequities through to the present day. As critical historical archaeologists, we see the relevance of these issues to our purpose in conducting our research.

How to study all this? We end with Laura McAtackney, whose work in Northern Ireland covers the Maze Prison and the murals on the walls that divide Catholic and Protestant public housing sections of Belfast. She gives us the lead on how to study the archaeology of imprisonment and on the formation of demonic personalities.

A critical archaeology begins by defining a part of a modern society that does not work right, often because of a group's impoverishment. The "why" is the job of historical archaeology and leads to a locus in the past that we can call an archaeological site. The act of excavation is always one of explanation, through archaeology, to the exploited and to the exploiting, in the hope that the exploiting can eventually realize that, if they don't reform ...

Empiricism

MARKO M. MARILA

University of Helsinki, Finland

Empiricism is the philosophical outlook believing that the origin of all knowledge is based on our sensory experience. As an epistemological view regarding the source, constituents, and limits of knowledge, empiricism dates back to antiquity, reverberated through the Middle Ages as the Aristotelian maxim “there is nothing in the intellect that was not first in the senses.” As such, empiricism can be regarded as a counterpoint to rationalism, the philosophical view made famous by Descartes in the early seventeenth century, which in stark contrast to empiricism maintains that reliable knowledge is achieved by rational contemplation alone.

During the seventeenth and eighteenth centuries, philosophical empiricism developed into empiricist forms of idealism and skepticism mainly through the works of early British empiricists Locke, Berkeley, and Hume. While their philosophies differed greatly, their common conviction that “there are no mental contents that cannot be derived from sensation or reflection” identifies all three as empiricists (Atherton 1999, viii). To this end, Locke, for example, held that knowledge is limited to the perception of ideas provided by our senses, and things external to sensation cannot be known. Berkeley adopted a more radical ontology. He argued that in order for anything to exist in the first place it had to be perceived by a sentient being. Perception, for Berkeley, is perception of sensations and ideas rather than of external material objects.

An important aspect in Hume’s philosophy regards the relationship between observation and expectation. Hume saw imagination rather than reason as the operation by which the mind generalizes from observations, and doubted the justification of conclusions from experience. This doubt and the foregrounding of imagination rather than reason as the source of expectation

constitute part of Hume’s skepticism toward the *inductive method*: An inductive argument supposes the generalization it aspires to establish and is therefore circular.

In the beginning of the twentieth century, empiricism was revitalized in the form of logical empiricism (see POSITIVISM). In general, logical empiricists shared an aversion toward metaphysical speculation and regarded observation and formal logic as means to justified knowledge. For logical empiricism, the scientific method differed from Newtonian induction. Instead, logical empiricism adopted the *hypothetico-deductive (H-D) method* in testing knowledge claims (see HYPOTHESIS TESTING). In this setting, knowledge was conceptualized as limited to observational propositions, and the validity of each proposition was assessed by its correspondence with hard empirical evidence. In other words, logical empiricism presupposed a natural unity between meaningful language and empirical facts. If a statement did not correspond to the observed facts, it was false, or meaningless at best.

Another attempt to reconcile rationalism with empiricism was classic American pragmatism, most notably formulated by Charles Peirce toward the end of the nineteenth century. Based on the philosophies of Kant and Hegel, Peirce’s philosophy formed a systematic critique of Cartesian rationalism and skepticism. Most importantly, American pragmatism attempted to transcend the real–ideal, mind–body, and material–immaterial dualisms inherent to both rationalism and skepticism by conceptualizing interpretation and the formation of knowledge from the viewpoint of biological evolutionism.

Informed by evolution theory, Peirce saw science as a self-correcting historical process. He stated that the objective of scientific inquiry is the gradual fixation of belief through induction. Beliefs can become indubitable for a number of undesirable reasons (popular beliefs held by the masses, or social force implied by an authoritative class of thinkers), but at times a surprising fact will force a revision of those beliefs. In pragmatist terms, induction depends upon the

confidence that a run of one kind of experience will not change or cease without some indication before it does so. Successful anticipation of these discontinuities in experience is essential to knowledge formation. For Peirce, the history of science had demonstrated that the probability in the long run to guess right far exceeds random luck.

Peirce introduced *abductive inference* as an essential logical function in hypothesis formation through guessing. When making an abductive inference, then, “we are bound to assume, independently of any evidence that it is true. Animated by that hope, we are to proceed to the construction of a hypothesis” (Peirce 1958, par. 219). In contrast to formal logic, Peirce’s extended view of logic adopted an empiricist attitude toward knowledge production, and abduction became one conceptualization of the logic of discovery and for the role of creativity (see CREATIVITY) in it.

Empiricism and archaeology

Due to the concrete nature of archaeological materials, empiricism forms a central theme in the epistemology of archaeology. Empiricism in archaeology, however, most often entails the conviction that the archaeological data can speak for themselves with no need for theorizing from the archaeologist’s behalf (Johnson 2011). Empiricist approaches in archaeology have tended to stress the relevance of excavation, data analysis, and common sense rather than theory or philosophy as primary sources of archaeological knowledge. Therefore, when speaking of empiricism in archaeology in particular, a distinction should be made between being empirical and being empiricist. While archaeology in general is empirical due to the nature of archaeological evidence and the hands-on character of its methodology, empiricism denotes a more specific genealogy of the epistemology of archaeology.

This genealogy has its roots in antiquarian and culture-historical archaeologies. These traditions are often referred to as naively empiricist because of their reliance on the inductive method. In this setting, archaeology centered collecting, with little regard for theory or source criticism.

Antiquarian and culture-historical archaeologies can therefore be seen as total archaeology that regarded the past as a collection of materials that had to be secured in their entirety before any general idea of the past could be reached. The view of nineteenth- and early twentieth-century archaeology as theory-free is, however, misguided because many archaeologists of that time also acknowledged the subjective extent of archaeological knowledge.

Epistemological issues about the limits of archaeological inference became increasingly addressed in archaeology around the mid-1900s. British archaeologist Margaret Smith (1955), for example, remained skeptical about the possibility of positive archaeological knowledge. The absence of a logical relationship between past human activities and the visible evidence that survives only partially led Smith and many others toward epistemic pessimism, especially when addressing questions that dealt with the less concrete aspects of past lifeways such as politics and religion. In essence, due to the lack of logical certainty between archaeological observation and archaeological explanation, Smith deemed archaeological inference a hopeless task. These developments led some archaeologists to call for more work on the explanatory level in the form of processual interpretation.

During the latter part of the twentieth century, processual explanation became a principal objective of New Archaeology. The proponents of New Archaeology adopted a more optimistic attitude toward epistemology and the role of theory in archaeology. In order to free archaeology from subjective speculation, the discipline was taken to follow the rigor of natural sciences rather than the descriptiveness of cultural history. The objective of New Archaeology was to render archaeology explicitly scientific by constructing an archaeological theory on the solid foundations of the logical empiricist conception of science (Gibbon 1989). One task of New Archaeology was to establish cultural laws analogous to their natural counterparts that could be used to explain unambiguously the unobserved cultural and natural processes relevant to the production of the observed fragmentary archaeological materials. Americanist archaeology in particular turned increasingly

toward anthropology in the construction of bridging middle-range theories between material culture as data and theories of past living culture (see *FORMATION PROCESSES*).

In the course of the twentieth century, logical empiricism faced increasing critique and gradually lost its appeal among archaeologists. Within the epistemology of archaeology, the liveliest critique was targeted against the vague formulation and the imagined neutrality of the H-D method adopted by many new archaeologists. Archaeologists were quick to point out that the H-D method was oversimplified, and actually utilized a range of inductive generalizations as well as analogical inferences. Archaeology was demonstrated to hinge on the supposed reality of a range of theoretical terms that do not correspond to any directly observable data. While a position by no means welcomed uncritically by all new archaeologists, the logical empiricist separation of theory from observation was subjected to fervent critique. Interestingly, one of the key figures of New Archaeology, Lewis Binford, argued that archaeological knowledge is a product of inferential reasoning rather than direct observation. Telling of the complex role of empiricism in New Archaeology, then, was Binford's repeated insistence that everyone was an empiricist apart from himself.

Increasingly, during the 1970s and the 1980s, archaeologists began to notice that observations are intimately theory laden and dependent on the social, cultural, and political context in which they were made. With the advent of post-processualism, many of the core assumptions of logical empiricism, such as the correct scientific method and the unity of sciences, became replaced with anti-positivist and constructivist alternatives, and philosophy of science went out of fashion in archaeology. Instead, archaeologists turned to semiotics and phenomenology for interpretative inspiration (see *INTERPRETATION*).

During the twenty-first century, archaeological empiricism has shown symptoms of revitalization. This development has happened on two interconnected fronts. On the one hand, the rapid development of exact natural scientific methods offers an attractive alternative to the atomized and at times confusing field of archaeological theory. Natural scientific methods yield a wide range of unambiguous data that,

for many, can render epistemological reflection about the nature of archaeological interpretation redundant.

On the other hand, the ontological turn that has taken place in much of philosophy and social sciences has resulted in a return to empiricism in the epistemology of archaeology. The "ontologically responsible" (Marila 2017) new empiricism, inspired to a large extent by new materialisms (see *NEW MATERIALISMS*) and speculative realism, presupposes a close affinity between ontological and epistemological concerns. The problem originating in ancient Greece that what is known (the object of inquiry) is dependent on how it is known (the method of inquiry) is not seen as a research deficiency but rather adopted as an epistemological starting point. The new archaeological empiricism is based on a pluralized conception of interpretation and holds that things-in-themselves, as they exist outside human understanding, remain constructed through their shared relations with multiple interpreting agents.

In respect to the archaeological material, new empiricism aims to sidestep the anthropocentrism of both logical empiricism and social constructivism. In part, this development has been inspired by the realization that new observations of the archaeological record can be so radically different and downright weird that reducing their meaning to rational or social representation would violate them. As new types of materials such as ocean drift matter and nuclear waste become regarded as archaeologically relevant, such archaeological key concepts as time (see *TIME AND TEMPORALITY*) and origin but also the theoretical and methodological core of archaeology need revision.

In order to react to the unexpectedness of the past, some realist archaeologists are turning to abduction instead of induction or deduction as an open-ended and speculative epistemological model for the logic of discovery and the formation of new archaeological knowledge. As a combination of empiricism and phenomenology, archaeology's new empiricism stresses the aesthetic and vague extents of knowledge formation as opposed to the view of the scientific method as inherently exact and rational. Perhaps somewhat ironically, then, philosophical new empiricist archaeologies continue

the methodological anarchism introduced in archaeology by post-processualism.

Environment and Landscape

BRUNO DAVID

ARC Centre of Excellence for Australian Biodiversity and Heritage, Australia

DUANE W. HAMACHER

Monash University, Australia

It is not unusual in archaeology to begin the study of a site or region's history by reviewing or giving some kind of account of present-day, and past, environmental conditions. This often includes the geology, vegetation, and fauna, along with climate, and, on some occasions (such as at Newgrange, Knowth and Dowth in Ireland, Stonehenge in the United Kingdom, and some ancient Pueblo sites in the four-corners region of the United States), astronomical observations. These descriptions are usually presented as external conditions that help us better understand the physical contexts of the cultural sites in question. We thus describe the topography, soils, trees, and animals, rainfall and temperature, even the sun, moon, and stars, as a way to better identify the regional contexts of archaeological sites, and how those sites sit in a broader physical universe. We do so to better identify those outside conditions within which people are located—the “where” of the places that people did things in the past. Such descriptions of the physical environment are presented as a way to better understand the physical conditions that affected human actions. People did things through a combination of conscious intentions and subliminal influences, and those environments affected their decision making as constraints and opportunities of living in a material world.

Yet there is a problem with this view of human actions in the environment. In trying to understand the physical conditions of engagement—as this essentially divided dual “environment/people” way of conceptualizing human actions in place does—what we attempt

to understand are landscape engagements that are rich in cultural *meaning*. It is through this meaningfulness that people created individual archaeological “sites” as particular positionings of social actions. And it is also through meaningful emplacement that relations with nearby and more distant features (including other “sites”) are formed. Those meaningful locations are places whose social and cultural sensibilities archaeologists try to understand.

The concept of “landscape,” here used as shorthand for the totality of “scapes,” includes the land, water, and sky. The term “landscape” was first introduced into the English language during the late sixteenth century, when Dutch *landschap* artists depicted rural vistas as visual representations of domestic country scenes. Since the 1980s, Anglophone archaeologists in particular have become increasingly interested in anthropological and philosophical notions of “dwelling” (Ingold 2000) and “inhabitation” (Thomas 2008)—that is, of how cultures and social actions are located in particular world-views (ontological relations), of how human actions are acted out in a world made sense of through its meaningfulness, and by how the world is rendered in culture. No longer do we tend to reduce the past to the actions of “humans” who are more or less biological automata, individuals and individual societies who simply act to survive and whose behaviors at any point in time and place can be worked out simply by understanding the physical environments in which they hunt, gather, raise livestock, or grow crops. We have come to examine relationships between people and between people and things, how in the past people actively engaged in a meaningful world through the way they understood it to operate, and through how it is represented in culture. French archaeologists employ a term, “*le geste*,” to denote this human touch in, and of, the world. It is a useful word, without exact equivalent in English, although “gesture” comes close, because *geste* denotes how the things we do are socially inscribed with meaning. We can think of the hand that paints as a *geste*, as are the actions that lead to the making of a site. These involve intended, culturally

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

DOI: 10.1002/9781119188230.saseas0215

informed, and socially sensitive actions, even if subliminal forces are also at stake and if the outcome is not exactly what was intended at the start. Archaeological objects, and archaeological sites, are gestural signatures; they are the “scapes” of cultural actions. This, then, becomes the key difference between the “environment” and “landscape” of the language of archaeology: At first the word “environment” was adopted as a way of describing the physical environment that surrounded and affected human actions; and, later, “landscape” emerged as a way of nuancing more the notion that from the outset people are born into already-meaningful worlds (sometimes explicitly expressed in Heideggerian phenomenological terms, as “being-in-the-world”), so that to understand actions we need to understand their meaningfulness as much as we need to understand the material properties of things.

Let us give an example of how place is inhabited in this cultural way, how its imbued social meanings help structure social engagement, by reference to Australian ethnography. Our aim here is to demonstrate how what is often thought of as external environment is in fact more than this when dealing with the actions of people, with human *gestes* and cultural history. Landscapes are meaningfully engaged and understood through world-views that we can think of as both ontology (the way we understand the world to *be*) and cosmology (in archaeology, this term is usually used in a way that nuances the mysteries and esoteric/spiritual constructs of cultural groups, unlike in western astrophysics where it refers to those dimensions of astronomy that concern the physical structure and evolution of the universe). Those world-views guide the ways people think about and act, so much so that archaeological sites become structured not just by the lay of the land as physical phenomena, but by the lay of the land as ontologically ordered phenomena.

The anthropologist Marcia Langton (2002) gives a useful night-sky analogy to illustrate the point. What we see in the sky are not only planets, stars, and other physical bodies, but something much grander: a confirmation of what we already know about how the world operates—time, life, our place in the universe. What we see as tiny bright dots on a black, blank canvas, we know to be gigantic balls of fire whose light emanates across space as time progresses, literally at the

speed of light, reaching us in the here and now as the night-sky that we gaze upon. It is not simply that we see these cosmic realities with our own eyes and so we believe, but rather we already understand this to be the case as we gaze at the stars; the stars are already there as meaningful entities. What we see is not abstract visual space, but rather cultural places already rich in meaning, in this case informed by astronomy and related disciplines.

But this is not the only way of seeing the night-sky. In Aboriginal Australia, the trees and hills and fauna, and the stars, are emanations not of western botanical, geological, zoological, or astronomical knowledge, but of the numinous ancestral forces that give shape to place as *country*, the meaningful homeland into which all things are given their defining characteristics in the creative events of “the Dreaming,” a landscape that is as much kin as it is “environment.” Those kin relations that people have with the sky, for example, affect everyday life here on earth, for they intimately connect people with topographic features created by the ancestral beings. All of society is implicated by those features, because the ancestral beings have particular kinds of relationships with everyone (everyone is connected with individual places through those particular ancestral connections), and everyone is connected with each other in specific ways. Those connections demand exacting forms of behavior—the social rules and guidelines reported by community members and social anthropologists. The ontological, social connections between people and features of the landscape affect what people do in particular locations, and this helps structure the archaeological record of each and every site.

For example, in the ethnographic traditions of Australian Aboriginal and Torres Strait Islander cultures, social life (including, but not reducible to, subsistence) is intricately linked to the sky. Many traditions explain that what is on the land is connected to, and reflected in, the sky. Torres Strait (the island-clad sea between northeastern Australia and the southern New Guinea coast) Islander ways of being and ways of knowing are closely connected to the stars. Islander cosmology is based on the story of the culture hero Tagai (Sharp 1993). Tagai was a great fisherman and warrior. During a fishing expedition with his crew

of twelve men (Zugubal) and his first mate Kareg, Tagai searched the reef for a suitable fishing spot. Hot and frustrated, the Zugubal consumed Tagai's rations, angering him upon his return. Tagai killed the Zugubal, who were cast into the sky (after being drowned) as two groups of stars: Usiam (the Pleiades star cluster) and Utimal/Seg (the belt and scabbard stars of Orion). Tagai and Kareg went to the opposite side of the sky to keep away from the selfish Zugubal. Tagai comprises several western constellations spanning across the sky from the Southern Cross (Crux) to Corvus, standing on his canoe (Scorpius) with Kareg (the star Antares) at the stern.

The story of Tagai encompasses themes that provide instruction for laws and customs that inform Islander identity and spirituality. These themes influence social-cultural traditions, but also describe knowledge about the interplay between Islanders and the places in which they live (Sharp 1993, 3–5). The Tagai narrative establishes connections between the rising and setting of stars at dusk and dawn throughout the year and their connection to changing seasons, which inform weather, climate, food sources and means of procurement, social events, and how people see the world to operate generally. In doing so, they affect how people engage in places, and thus how and why (archaeological) sites are formed. Islander epistemologies draw upon causal relationships between the land and the sky. For example, as the Zugubal rise in the evening sky, they announce their presence with thunder, signaling the coming of *kuki*, or monsoon season (Eseli et al. 1998). During this time, Tagai and Kareg set in the west. As they set into the sea, they splash water into the sky, which falls as the rains of the monsoon season (Sharp 1993, 60).

This knowledge is encoded in song, dance, and ceremony, which incorporate masks and dance machines and are often performed at sacred sites at significant times of the year. The Kek ceremony on Mabuyag is performed when Kek, the yam star, rises in the dawn sky just before sunrise (Haddon 1904, 339). Regarded as the Islander New Year by many communities, the rising of Kek at dawn signals the approaching dry season, the southeasterly winds, and the time to harvest yams. The Kek ceremony is performed at a site on the southeast coast of the sacred islet of Pulu off the western coast of Mabuyag. It serves as

a sign of thanks and as an increase ceremony. The ceremonial ground on Pulu faces the star as it rises in the southeast over Baudhar (Mount Augustus) on the nearby island of Mua (Haddon, Rivers, and Ray 1912, 223). This is all part of the Torres Strait landscape, but in archaeology it would not normally be treated as a description of the environment.

Similarly, in Aboriginal traditions of the ethnographic period across much of Australia, ancestral beings created the world before ascending to the sky, where they watch over the world as stars and planets. Their actions are often denoted by transient celestial events, such as comets, meteors, aurorae, and eclipses, particularly as warnings to obey sacred law. Many beings are represented not by constellations of stars, but by “dark constellations” traced out by the dust lanes in the Milky Way. Among the best known and widespread examples is that of the celestial emu. The emu's head is represented by the Coalsack nebula, which borders Crux. The neck stretches down through the constellation Centaurus and the flightless bird's body is the galactic bulge of the Milky Way in Scorpius, with its legs stretching down through Sagittarius.

In Euahlayi traditions of northwestern New South Wales (Fuller et al. 2014), the emu first appears in the evening skies during April and May as a female chasing a male for mating. In June–July, when the emu is higher in the sky, it represents a male sitting on the nest. This is when eggs can be collected as a food source. In November, when only the bum of the emu is visible in the sky, the emus are sitting in waterholes. In the summer, the sky emu mostly disappears, meaning the emus are leaving the waterholes as they dry up (Figure 1).

The celestial emu also informs ceremony through connections between the land and the sky. Many initiation sites in southeastern Australia comprise two circles connected by a pathway. The ceremonial ground is reflected in the Milky Way as the celestial emu (Fuller, Hamacher, and Norris 2013). Many initiation ceremonies in southeastern Australia are held when the sky emu aligns with the terrestrial ceremonial ground as they link on the horizon in the southwest. This coincides with August and September, when emu chicks have hatched

and are nurtured by male emus. This symbolizes the elder men bringing the boys into manhood through initiation.

Many of these ceremonial sites have been identified and mapped during field surveys by archaeologists. Today, we make sense of them through the ways people engaged with *their* world—that is, through notions of “landscape” as cultural constructs, more so than “environment” as fixed and all-endearing entities—for it is in the way that people related to the stars, to the land, and to each other as connected beings that the archaeological sites can be understood as

social and cultural places. Landscapes express place and emplacement as ontologically informed and socially engaged. And, through time, it is those shifting constructs that archaeologists investigate. We can, and do, look at all kinds of places through this landscape lens: at broad geographical scales, how people interact across wide expanses of sea, such as in the western Pacific where Lapita colonizers made far-flung places their own, culturally and socially domesticating space in the process. At a smaller geographical scale, we explore how new social worlds were made when people built stone or earth channels

Figure 1 Changing view of the emu in the sky, according to Euahlayi Aboriginal traditions (New South Wales, Australia). (a) Female emu chasing a mate. (b) Male emu incubating eggs. (c) Eggs hatch and male emu begins rearing the young. This occurs during the time of year when male initiation ceremonies are undertaken. Sacred *bora* grounds where initiation ceremonies are performed align spatially with the axis of the celestial emu, which itself represents the sky *bora*, creating a pathway from earth to sky through the Milky Way in the southwest. Here the place of social activity (identified by archaeologists as a particular kind of “site”) was created by reference to local indigenous cosmologies. (d) Emu sitting in a waterhole in late spring. The emu leaves the waterhole as it dries up in summer; this is a time when the celestial emu dips below the horizon.

as conduits for flood waters populated with eels, allowing the mass capture of eels and creating new seasonal schedules and networks of social interaction in the process (e.g., McNiven et al. 2012). At a smaller scale still, individual sites are now examined for how people are implicated in them, and, in doing so, how the very fabric of the sites progressively changed and grew through those social engagements, such as at Nawarla Gabarnmang (Australia) and Chauvet Cave (France) (Delannoy et al. 2013) and barrows of the British landscape (e.g., McFadyen 2008). The archaeological sites are architectural locations where people undertook, and engineered, socially and culturally meaningful actions. In “landscape,” the environment is not simply outside, but also inside; nor is it simply about the navigation of terrain towards the consumption of “resources” as food—the starscapes of Torres Strait Islander and Aboriginal peoples illustrate this point nicely. Rather, by examining spatial and temporal patterns in the products of past social and cultural engagements at varied geographical scales, the history of the meaningfulness of “the environment” as landscape, of the *gestes* performed, allows us to better understand the human past.

Ethics in Conservation

MICHAEL A. DI GIOVINE

West Chester University of Pennsylvania, USA

TERESITA MAJEWSKI

Statistical Research, Inc., USA

Ethics are future-oriented rules of behavior based on ideas about what are morally correct actions—those that are right, just, and good, and create just actors in return. Codes of ethics are sets of rules agreed upon by a particular group, and when ethical positions are stated, it is important to provide context for the group and their beliefs. As a practice aimed at long-term safeguarding, preserving, and communicating heritage values to present and future generations, heritage conservation, particularly in heritage practice or management, is intimately tied to ethics, and is often spoken about in moral terms as ensuring the public good. Yet the nature of heritage, as well as the complexities of conservation in specific contexts, makes the application of ethical principles in actual practice quite challenging. While heritage purports to be inclusive—it links people with a recognized claim to an object, site, or intangible production through time and space—it does this by being necessarily exclusive; heritage claims identify the object as being valued and meaningful to a specific group and thus not to others. Conservation practice therefore entails remembering, emphasizing, and prioritizing certain narratives about a heritage property while forgetting, deemphasizing, and marginalizing others. Conservation practice can also be physically destructive: as particular qualities are preserved and enhanced, physical elements testifying to other phases of the object's life history are removed and destroyed. That these actions are just or unjust is not inherent, but are situationally determined through what ethicists call “morality.” The difference between ethics and morals is that ethics are philosophical ideals guiding social actions, while morals, which are linked to

the norms of society or particular groups within societies, are the ways in which ethical ideals play out in specific instances. The challenge in heritage conservation is to identify an overarching ethical stance that can accommodate different, and sometimes conflicting, practical applications.

Because of the complexity of heritage conservation and the many actors that are affected by it, groups involved with conservation activities (here more broadly defined as heritage preservation/heritage management) have developed codes of ethics that serve as general guidelines to regulate specific activities. They regulate ideas of ownership, use, and communication of heritage values, and often identify these by specific groups of stakeholders. From a discursive perspective, the original, often indigenous producers of tangible or intangible heritage are usually the primary stakeholders defined. But in reality, a broader definition of stakeholder could include the proponent of an activity (e.g., a developer, bank, community, government agency/entities), places where heritage materials are “stored” and/or exhibited (e.g., museums, archives, libraries, and other types of repositories), entities that manage or interpret heritage (e.g., heritage management firms, universities, site managers, travel industry professionals), entities that have a mission to “safeguard” heritage or a philanthropic interest in it (e.g., professional societies, nonprofits, including nongovernmental nonprofit organizations, religious institutions, and intergovernmental organizations (such as the United Nations' Educational, Scientific and Cultural Organization [UNESCO] and its professional advisory bodies like the International Council on Monuments and Sites [ICOMOS] and the International Union for Conservation of Nature [IUCN]), organized conservation or heritage societies, conservation-minded donors), and the many publics that “consume” heritage (e.g., tourists, pilgrims, government agencies/entities, taxpaying citizens). If the desired outcomes of situations are always focused on the “best” or most appropriate treatment of tangible or intangible heritage resources, then ethical practice would

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

© 2018 John Wiley & Sons, Inc. Published 2018 by John Wiley & Sons, Inc.

DOI: 10.1002/9781119188230.saseas0230

be more straightforward. But herein lies the crux of the problem—almost all of the stakeholders have conflicting, often quite different ideas about the most desirable outcome(s) from their perspectives. These center around disagreement regarding the value, ownership, and uses of heritage, and the appropriate ways to communicate and “manage” it. Stakeholders often struggle and negotiate with each other for power to dictate the outcomes of these areas of conflict.

Di Giovine (2015) lists three different ethical paradigms in conservation practice: paternalistic, multicultural, and patrimonial. Paternalistic ethics are in play when those in privileged and/or dominant positions assume a stewardship role over the heritage property and its conservation plan. As these are often archaeologists and heritage managers—the community of practice invested with the authority to care for these properties—they are frequently informed by a Eurocentric worldview that privileges care for the authenticity and integrity of the material. This object-centric worldview comes into conflict with other stakeholders’ worldviews, such as those in concept-centric societies, as discussed by Christina Kreps (2003, 46–48). Buddhist practices, for example, are guided by an understanding of the impermanence of life, and therefore often let what would be considered heritage resources naturally decay. Deeper cognizance of differences and self-reflexivity in archaeology in the latter half of the twentieth century has fostered what Cristóbal Gnecco (2014) considers to be multicultural ethics, which aim for more inclusivity and consultation in decision-making processes. Yet multiculturalism comes with its own critiques, as it emphasizes the “otherness” of nondominant stakeholder groups, and, in doing so, solidifies the hegemony of the dominant group. As a response to this, patrimonial ethics is a paradigm that acknowledges the life history of a tangible or intangible heritage resource (e.g., an object, building, site, landscape, or custom) and its multiple and negotiated uses and meanings. To better understand what kind of actions are just and good toward a heritage resource in its present state, stakeholders would be identified and meaningfully empowered to determine the heritage property’s conservation outcome.

Paternalistic ethics

Paternalistic ethics are those idealized actions that position the conservator over other stakeholders as a privileged, guardian figure toward the material protection of cultural property. Inasmuch as archaeological, museological, and artifact/document conservation practices have their origins in western, European history—and are exported throughout the world via globalization as a marker of modernity (Kreps 2003)—it continues to be the hegemonic ethical orientation for conservation practice today.

Like anthropology and archaeology, the development of the heritage industry and conservation practices are deeply rooted in the nineteenth-century colonial system and its paternalistic quest to civilize and modernize native groups who were perceived to be evolutionarily behind that of the West. The changes the colonial system wrought on perceived traditional ways of life, coupled with fin-de-siècle fears of their own societal decadence and loss at the hands of modernization and industrialization, produced the impetus for salvage or rescue archaeology and conservation in the late nineteenth century, and influenced future perspectives on responsible management of the archaeological record. The earliest uses of the word “heritage” (in England) or *patrimoine* (in France) referred to the creation of a national office to protect historic monuments and artifacts—a dual process of recovery (i.e., excavation and conservation/preservation) and discovery (i.e., archaeological and historical practice aimed at fleshing out the roots of modern society). Furthermore, informed by Enlightenment-era notions privileging the visual over other senses, Victorian-era scientists and early museum curators also espoused the philosophy that an object (or fragment) can elucidate obscured historical, cultural, and biological facts if interpreted by a trained expert. There was little reflexivity as to the subjectivity of the expert interpretation. Such a notion privileged material authenticity and integrity, and largely influenced developing notions of western notions of stewardship.

Artifact-centered, the paternalistic ethic of conservation was, and continues to be, motivated by a notion of “risk,” of a threat to the integrity

of an object by outside forces (including time itself). It is because of these risks and threats that heritage properties are considered to be of heightened value. Conservation and heritage resource management developed significantly in the second half of the twentieth century, as practitioners sought to salvage and restore cultural properties damaged as a result of devastating warfare, and as newly independent colonial states began to see their traditional heritage as valuable resources, particularly in raising development funding and in capitalizing on the growing tourism industry. At the same time, legislation designed to protect and manage heritage before it was destroyed by development or other means began to be enacted throughout the world.

Representing the culmination of these movements, UNESCO ratified the 1972 World Heritage Convention, which saw cultural heritage as a prime mobilizer of global solidarity and thus of fostering peace at the grassroots level. UNESCO had successfully mobilized the international community to save the monuments of Ramses II in Abu Simbel, Egypt, which would have been destroyed by the construction of the Aswan High Dam, and then raised funds to “Save Venice” from rising floodwaters. As both of these catastrophic events generated impassioned responses from nonlocal people at the grassroots level, UNESCO saw the potential in creating global solidarity by constructing an international consensus of certain sites’ “universal value,” and therefore of the collective responsibility for safeguarding them. The World Heritage Convention—and its associated Intangible Cultural Heritage Convention in 2003 protecting traditional practices and performances—are therefore ethical documents, paternalistically aimed at “responsibilizing” populations (Ilcan and Phillips 2006, 64) and motivating them to act in ways that are right, good, and just—not only toward the heritage resource itself, but also toward one another.

Despite a greater emphasis on diversity and acceptance of many societies, UNESCO and its Advisory Body, ICOMOS—like other conservation organizations—employs a paternalistic ethic toward conservation. World Heritage properties are evaluated against a rubric that specifically assesses the authenticity and integrity of material remains, as well as how effectively the property reveals, or illustrates, historical or cross-cultural

connections. Despite an increased awareness of the role of local communities in heritage conservation, World Heritage Sites’ nomination, designation, and care are ultimately in the hands of the nation-state, which works with these supranational organizations in designing conservation plans. Furthermore, the unit of measurement of this ethical paradigm focuses not on the preservation of indigenous community or diverse cultural groups per se, but of a hegemonic community modeled in the likeness of UNESCO. This community is not a traditional empire or sovereign nation-state, but what Di Giovine (2009) has called the *heritage-scape*: a dynamic, borderless imagined community predicated on the ritual reappropriation and juxtaposition of tangible heritage sites.

Multicultural ethics

Following the reflexive turns in historiography and anthropology, and born of the Euro-American “multiculturalism” movement of the second half of the twentieth century, heritage theorists have become critical of their disciplines’ own historical role in the colonial (and now neoliberal) endeavor, as well as their own paternalistic ethics marking their work, which solidify authorized or official discourses about the heritage property. As a result, archaeological and museological societies have embraced what Gnecco (2014) termed “multicultural” approaches, which aim for inclusivity in conservation practices by involving local actors in conservationists’ projects (often as a labor force), opening local museums for the benefit of making their finds more accessible to the surrounding population, and integrating alternative historical understandings in their interpretations. Seemingly in contrast with paternalistic ethics, Kreps (2003, 10–11) argues that “new museology,” which embraces a multicultural paradigm, is “people-centered and action-oriented” and suggests co-curation and other forms of indigenous involvement in the conservation and exhibition processes.

While multicultural ethics embrace inclusiveness and diversity of perspectives, critics like Gnecco note that it does little to change

conservation in practice. Like Talal Asad (1993), Gnecco (2003, 20) points out that multiculturalism also traces its origins to the colonial era, in which diverse “others” were “clearly defined, delimited, separated” and stereotyped so as to facilitate their assimilation into the dominant culture under the rubric of “diversity.” For Asad (1993, 245), multiculturalism acknowledges that these clearly defined minority groups are given “the right to make a contribution” to society by the dominant culture. Terrance Turner (1993, 414) argues that, at best, multiculturalism can be conceived of as “an agent of change” in indigenous societies that provides a framework for contesting hegemonic influences, or at worst becomes “difference multiculturalism” aimed at reifying and fetishizing ethnic or cultural differences that give license to political and ideological separation. Either way, despite the oft-good intentions of conservationists, multicultural ethics—predicated as they are on identifying “cultural difference” within a culturally dominant society—often thus serve to extend the hegemony of the dominant group, because, ultimately, the hegemonic power determines the norms and values to be incorporated and coordinated. With this paradigm, conservators and heritage managers run the risk of imposing their “multicultural” values on other groups that may not share it. Ensuring that other groups are consulted, that others are educated or provide input on conservation practices, or that the practices benefit locals continues to position conservators as the patriarchs, so to speak, in the paternalistic ethical paradigm. Multicultural ethics often create, or perpetuate, the very tensions that it purports to resolve.

Patrimonial ethics

Both ethical paradigms seem to moralize conservation and thus valorize conservationists and, at the same time, call into question the morals of preservation practices as they affect others. Both therefore tend to obscure or lose focus on the heritage object itself. Patrimonial ethics, however, are centered on a more robust understanding of the totality of stakeholder groups in a heritage discourse, and refocus on the heritage property (Di Giovine 2015). They recognize that, as Pierre

Bourdieu (1993, 34–35) states about a work of art, a heritage object is not the product of a single author or stakeholder community, but the “result of coordinated activities of all the people whose cooperation is necessary in order that the work should occur as it does.” He defines these coordinated activities—and the socioeconomic space that contains them—as a field of cultural production. The perspective of patrimonial ethics thus sees broader relationships between the object and its stakeholders, and between the symbolic and lived uses of the heritage property.

Stemming from the notion that heritage objects or resources gain meaning through their social contexts and uses, patrimonial ethics treat them as social actors in their own right, able to impact and shape social relationships. Patrimonial ethics look to prescribe appropriate treatments of the object as well as how to act toward other stakeholders. This requires a more expansive understanding of the history and social structure of conservationists’ engagement with the heritage object as taking place within a field of production through which a variety of stakeholders are involved in constant struggles and negotiation regarding the meanings, values, and usages of particular heritage sites. It also understands that there is not one “heritage industry” or a universal guideline on ethical conservation practices, but rather that each heritage site or object is situated in its own context, and that each has a unique field of stakeholders. Each of these stakeholders constitutes a particular community of knowledge and practice, and the object can assume multiple meanings and uses depending on the different bodies of knowledge associated with it. Understanding that conservationists/preservationists represent but one out of many stakeholders in this field, and that they espouse but one body of knowledge concerning the object, a patrimonial position on heritage is more reflexive and seeks to assess key players and their engagements with each other and the resource itself. Furthermore, because it focuses on the good of the object, rather than solidifying the hegemony of the conservation community, patrimonial ethics should empower (not simply “involve”) local communities to determine the key significances of the object to be conserved. This does not mean that the community’s decision always takes precedence—frequently not

all stakeholders' ideas will align—but that there should be true negotiation of, and co-creation of a plan for, conservation. Rather than beginning with the assumption that alternative voices should be integrated into a preexisting conceptual framework, patrimonial ethics consider that there are multiple architectures of significances that will inevitably overlap—and that understanding this will better inform what is “right, fair, just, or good” for the object and the other stakeholders in a particular context.

Challenges

In practice, applying the tenets of patrimonial ethics will be difficult in cases where heritage practice already dictates, often within the context of legislation, how stakeholder interaction will occur and how decisions regarding heritage conservation will ultimately be made and by whom. This also includes areas where democratic actions—such as voting on the removal of contentious monuments from the public sphere—may be marked by structural inequalities that favor dominant groups, or that are highly contested by different factions. Working within current established practice and taking opportunities to change or improve it by incorporating more reflexive positions will involve establishing and rebuilding current, often dysfunctional relationships among those involved in heritage conservation.

Ethnoarchaeology

JERIMY J. CUNNINGHAM

University of Lethbridge, Canada

Ethnoarchaeology is the ethnographic study of relations between people and material culture. It is a specialized ethnographic method developed to facilitate the use of ethnographic analogy in archaeological interpretation. Ethnoarchaeology as an iconic subspecialty in archaeology was given its most influential definition as part of the New Archaeology in the United States, but the more general tendency for archaeologists to critically investigate the sources of analogical inference by conducting ethnographic research has a much longer history and is found globally.

Ethnographic research by archaeologists developed primarily to address two issues that archaeologists have encountered in making interpretations about the past. First, archaeologists have expressed some anxiety about their ability to interpret the material record directly, that is, by using analogies drawn primarily from their own background experience. They worry that their standpoints in “modern” post-industrial societies leave them ill equipped to understand material patterns in the archaeological record that may reflect radically different lifeways, including “pre-modern” foragers, subsistence agriculturalists, and craft producers. As a result, archaeologists have sought to consult supplemental bodies of knowledge that might assist them to understand economies, social systems, political structures, and religious beliefs that are not part of their own cultural repertoire. Second, while cultural anthropologists, post-colonial researchers, and indigenous scholars have produced extensive literatures that shed light on other ways of being in a range of societies, they have tended not to investigate the material implications of the practices they describe. Insights from these studies have inspired theoretical innovations across the social sciences, but archaeologists find them difficult to apply systematically to

the interpretation of the archaeological record. Together, these two issues create a need for archaeologists to conduct their own forms of ethnographic research. Ethnoarchaeology might then be defined as ethnographic fieldwork by archaeologists who (1) investigate alterity by studying “others” with lifeways that are perceived to be both different enough from the experiences of archaeologists and similar enough to ancient settings to warrant investigation; and (2) carefully consider the material implications of the practices they document so their existence in the past can be inferred from archaeological remains. As Nicholas David and Carol Kramer (2001) have noted, this definition makes ethnoarchaeology an explicit attempt to expand the analogical consciousness of archaeologists.

At its core, ethnoarchaeology is a specialized subfield that aims to address archaeology's reliance on ethnographic analogies to interpret the archaeological record (Gould and Watson 1982). Analogy is the transfer of knowledge from a well-known source context to a lesser-known subject context, for the purposes of interpreting activities in the subject context. The transfer of knowledge from source to subject contexts begins from an initial abduction that suggests that some observed similarities between the two contexts makes them alike in other, often more fundamental ways. Testing is undertaken to assess the suitability of the original interpretation by seeking evidence for the additional similarities and differences that should be present if the original analogy is valid (Wylie 1985). In archaeology, analogical inferences are often based on similarities in material culture between contemporary and ancient contexts, which suggest that similar causal mechanisms were responsible for those patterns. The background theoretical interests of the interpreter, including existing theories about behavioral-material correlations, tend to define which similarities are considered significant enough to warrant further analogical treatment (see below). Interpretive security is then created for the initial inferences through subsequent analogically based tests that elaborate on the causal

DOI: 10.1002/9781119188230.saseas0232

antecedents for the material patterns under investigation, producing increasingly refined understandings of both contemporary and ancient settings (David and Kramer 2001, 47–48).

For example, cultural historical archaeology has often suggested that stylistic dimensions of pottery such as decoration reflect different archaeological cultures. Cultural historical archaeologists may then believe that an archaeological pattern in which unique decorative traditions are imbricated across an ancient landscape reflect the presence of distinct ethnic communities who trade pottery across supposed ethnic boundaries. The accuracy of this initial inference can be assessed through secondary testing both in the source context by ethnoarchaeologists and in the subject context by archaeologists. Ethnoarchaeologists might initiate targeted studies of craft transmission, production sequences, decorative symmetry, or ceramic marketing and consumption to document ethnicity's impact on ceramic production and distribution in a selection of contemporary societies. Archaeologists working on the subject side of the analogy can draw from this additional knowledge to further test their initial interpretation against the same ceramic collections by seeing if new lines of evidence support an interpretation of ethnic heterogeneity. Ceramic petrography might identify, for example, compositional patterns indicating different production sequences or distinct sources of raw materials, transforming an initial interpretation about ethnicity into a more precise assessment of communities of practice or systems of ceramic distribution. Beyond ceramics, testing on both sides of the analogical equation might shift to other materials that ethnoarchaeologists have shown can vary with identity, such as iconography, architectural styles, or cuisine. The testing of different lines of evidence in both archaeological and ethnoarchaeological settings may support, transform, or even refute the initial analogy.

Over the long term, these distinct source side and subject side tacks allow archaeologists to refine their inferences about the past. Analogical inference is key to a post-positivist approach to epistemology that builds interpretive security in archaeology by triangulating independent lines of evidence, each drawn from some component of

source-side analogical knowledge to understand both human action and material patterns (after Wylie 1985). Ethnoarchaeology and archaeology are thus complementary research strategies, and research interests in ethnoarchaeology necessarily mirror topical interests in archaeology. Historically, ethnoarchaeologists have emphasized studies of formation processes, activity areas, craft production, architecture, space use, subsistence practices, discard and recycling of artifacts, and typology (David and Kramer 2001, 14–31; Lane 2006, 406–416).

The emergence of ethnoarchaeology

Archaeologists globally have used ethnographic information to assist their interpretations. However, “ethnoarchaeology” as a distinct research strategy is most closely associated with the New Archaeology that appeared in the United States in the 1960s. New archaeologists and later processualists felt that ethnoarchaeology should produce middle-range theories, made up of behavioral–material correlates that would allow the archaeological record to be translated into the behaviors that were the focus of their epistemology. This view of ethnoarchaeology subsequently diffused globally as an interest in formation processes of the archaeological record.

The intellectual history for ethnoarchaeology, however, goes back to at least to the Renaissance and the sense that “others” encountered by European explorers might inform understandings of European pasts. Formal analogical parallels between archaeological and ethnographic communities became most clearly defined in the late nineteenth century with classic evolutionism. Lewis Henry Morgan and Edward Tyler argued that cultures accumulated cultural “germs” through time and went through a common set of evolutionary stages, stretching for Morgan from savagery through civilization. Living societies could then be a basis for interpretation of archaeological remains when they shared a similar stage of development. The turn of the century cultural historical anthropology of Franz Boas reflects a widespread rejection of this classical evolutionary tradition and its emphasis on comparative forms of analogy. Yet, ethnoarchaeology was

given its first formal definition at that time by Jesse Fewkes. Consistent with the broad tenets of Boasian culture history, Fewkes relied on direct historical analogies in which oral histories from Hopi communities were used to understand nearby Tusayan archaeological sites. Subsequent work by Maxine Kleindienst and Patty Jo Watson in the Near East and by Robert Ascher in Sonora initiated a tendency, still prevalent in archaeology, for historical ties to be the primary basis for analogical inference (David and Kramer 2001; Lane 2006).

Ethnoarchaeology as a focused research specialty emerged as part of the New Archaeology in the 1960s. The neo-evolutionary focus of the New Archaeology meant that societies were expected to be broadly similar when they shared common adaptive strategies and sociopolitical organizations, and thus general forms of analogy were once again encouraged. At the same time, ethnoarchaeology was given a key role in processual archaeology's broadly positivist orientation. Ethnoarchaeology would produce middle-range theories made up of behavioral-material correlations that could be directly inserted into archaeological testing regimes to produce a methodological form of objectivity (Cunningham 2009). The hope was that the behavioral-material correlates ethnoarchaeology identified would produce a nearly universal set of material translations for human behaviors. While source-side experimental work found material patterns that could be consistently correlated to human actions because they were prescribed by natural laws, such as those found in lithic usewear or organic residue patterns, ethnoarchaeology generally failed to identify similar correlates for more complex social phenomena. Instead, ethnoarchaeologists produced cautionary tales that showed the diverse ways that human actions impacted material patterns.

By the early 1980s, post-processual archaeology sought alternatives to the ecological determinism of the New Archaeology by exploring structuralist approaches to meaning through a series of ethnoarchaeological studies in east Africa and India (contributions to Hodder 1982). Later, post-processual work distanced itself from the term "ethnoarchaeology," which it attributed to processual archaeology's neo-evolutionism, and instead introduced "material culture studies"

for its own consciousness-expanding research. While processualists generally saw material culture as "symptomatic" of behavioral systems and ethnoarchaeology as a way of translating material patterns back into behaviors, post-processual research considered material culture as actively constitutive of social relations. It thus used practice theory as a framework for reading cultural meanings directly from material patterns. Post-processual archaeology's focus on European prehistory also meant that it was ambivalent about the need to use "others" as a source for analogies, and instead archaeologists drew from their own experiences in post-industrial European society to interpret Europe's more remote pasts. Frequently this was accomplished by using universal or nearly universal processes associated with materiality as a basis for inference such as objectification, inalienability, and material agency. The coupling of this approach with a relativistic epistemology also meant that post-processual archaeologists were not as preoccupied as processualists had been with verifying their interpretations using programs of source-side testing. Consequentially, ethnoarchaeology waned in post-processual archaeology as other forms of ethnographic research blossomed under different rubrics. These included not just material culture studies, but also ethnographic studies of archaeological practice and a series of well-developed research programs that integrated ethnographic, archaeological, and historical methods into detailed studies of the ties between contemporary experience and archaeological heritage, such as archaeological ethnographies and indigenous archaeologies (e.g., Hamilakis 2011; Politis 2015). While post-processual scholars generally avoid describing their work as being in any way "ethnoarchaeological," their suite of approaches nonetheless reflects parallel attempts by archaeologists to expand their analogical consciousness through ethnographic engagements.

Global ethnoarchaeology

Work outside the Anglo-American tradition has shown similarities and some important differences (see contributions to Marciniak and Yalman

2013). Globally, archaeologists seem to have responded to their sense of analogical myopia by carrying out ethnographic fieldwork and historical investigations. Continental European folk culture approaches to analogy developed early and paralleled culture history in the Americas. In Italy, Poland, Russia, Germany, Turkey, Egypt, and Bulgaria, rural peoples who maintained supposedly “traditional” lifeways were studied by archaeologists to provided source-side inspiration for archaeological studies. Typically, these studies emphasized craft production systems or subsistence practices such as peasant agriculture or pastoralism that were unfamiliar to archaeologists and seemingly reflected continuities from ancient folk cultures in the same region. This use of historically focused analogies was often sporadic, but in Germany “ethnoarchaeology” was part of a long history of research in ethnohistory that includes explicit concerns with analogy. By the 1980s, the Anglo-American perspectives on ethnoarchaeology began to influence local folk cultural approaches. In the Turkish context, ethnoarchaeology was introduced in part by foreign projects, whereas elsewhere it emerged among local scholars who began reading Anglo-American publications. The comparative late arrival of ethnoarchaeology in Italy and Turkey meant that processualist and post-processualist insights were often incorporated simultaneously and produced diverse forms of ethnographic research by archaeologists.

Other areas have developed and maintained distinct forms of ethnoarchaeology (again, see contributions to Marciniak and Yalman 2013). In Francophone Europe, logicist approaches inspired by J.-C. Gardin produced a vibrant tradition of research that uses formal interpretive procedures to identify analogs in ethnographic research and apply them archaeologically. These exist alongside an equally well-developed Francophone interest in the anthropology of techniques that uses *chaînes opératoires* to understand how production sequences relate to broader social phenomena. In the former Soviet Union, Marxist archaeology initially emphasized the reconstruction of the forces and relations of production by drawing analogs from a broadly comparative sociological approach rather than ethnography. This was later supplanted by the

stage-based approaches of historical materialism in which ethnographic populations and archaeological materials were considered generally comparable when they possessed the same mode of production. Recent Russian research combines archaeological and ethnographic research on specific communities alongside ecological and experimental studies. In China, a distinct approach to ethnoarchaeological research emerged early on and grew contemporaneous with, but independent of, ethnoarchaeology in the United States. It combined studies of local “traditional” populations, historical documents, and global ethnography to interpret the archaeological record in China. As with logicist approaches, Russian and Chinese researchers have often adopted formal methodologies to identify and apply ethnographic insights to archaeological materials.

Finally, ethnoarchaeology was introduced to Latin America in the 1970s in association with archaeological research on sites in the region. Politis (2015) identifies three trends in Latin American ethnoarchaeology, including work to discover behavioral–material correlations with wide applicability, the study of cultural meanings, and research projects that integrated archaeological and ethnographic analyses to produce “indigenous histories.” One of the more recent trends draws from Spanish ethnoarchaeology and embraces a distinctly critical and post-colonial orientation in which ethnoarchaeology serves the interests and needs of local communities (Politis 2015).

Critiques of ethnoarchaeology

Throughout its history, ethnoarchaeology has faced a dizzying array of critiques. The most recent of these target processualist archetypes that emerged in the New Archaeology and then influenced ethnoarchaeological work globally, even as it began facing critiques (described above) from post-processualism (Lane 2006, 404–6; Cunningham 2009; David and Kramer 2001). Beyond these, processualists who expected middle-range theories to appear chastised ethnoarchaeology for being too eclectic when it instead generated cautionary tales. The bases for

making initial analogical ties between source and subject contexts, what are often described as boundary conditions or arguments of relevance, has been consistently problematic (Wylie 1985; David and Kramer 2001). The “stages” used in classic evolution supported racism, the adaptationist focus of the New Archaeology seemingly affirmed a scientific functionalism, while the modes of production used in Marxist theory were often dehumanizing. Ethnoarchaeology has also been challenged on ethical grounds for studying contemporary peoples to create reconstructions of ancient pasts in which they have no stake. Direct historical approaches to analogy, such as those typical of archaeological ethnographies, indigenous archaeologies, and the indigenous histories of Latin America seem more ethically sound because they make analogical ties between archaeological remains and descendant populations who are partners in the research process. However, these approaches may rely on the belief that key components of economy, social organization, or ontology have survived colonial interventions and the depredation of capitalism. American cultural history and European folk history approaches risk treating indigenous peoples and rural agrarian communities as vestigial populations resistant to change, even though they are frequently citizens of the same nation states as the archaeologists who study them. In a similar vein, post-processual archaeologies that use the standpoints of post-industrial European scholars, rather than cross-cultural insights, to investigate ancient materialities seem to overlook the important Marxian insight that subjectivity can vary depending on one’s position in a specific mode of production, raising questions about analogical relevance. Finally, the principal textbook for the subfield has also stressed that ethnoarchaeology projects rarely match the ethical, methodological, or theoretical sophistication of self-reflexive ethnography (David and Kramer 2001).

These critiques are substantial and invite a broad rethinking of analogy and ethnoarchaeology. However, the suggestion that ethnoarchaeology should simply be abandoned (e.g., Gosselain 2016) overlooks its significance to the discipline as a self-critical, consciousness-expanding exercise that is wider in its scope than any one theoretical agenda. An archaeological discipline without some form of ethnoarchaeology

does little more than reify the ideologies of its practitioners, who demographically are still dominated by middle-class men from the global north. For archaeology to legitimately produce global histories, it needs to make inferences about the past that draw from an understanding of the full diversity of the contemporary human experience. Along with other forms of critical source-side work such as feminist scholarship, post-colonialism, and indigenous archaeologies, ethnoarchaeology is fundamental to expanding on the reservoir of analogical knowledge archaeologists use to interpret the past.

Evolutionary Theories

JOHN C. BARRETT

University of Sheffield, UK

Evolution is the process that enables internally generated change to occur in an organization over time. Most firmly associated with changes in systems of biological organization, evolutionary theories have impacted upon three different areas of archaeological research. They have provided for an increasingly refined understanding of the development of anatomically and behaviorally modern humans alongside the histories of our nearest hominin relatives, they have informed an understanding of the processes that might have resulted in different sequences of material cultural change where those changes have been taken to represent the transmission of traditions of behavior, and they have been used to evoke a logic in the development between different scales of social organization. The first two of these areas have variously drawn upon the neo-Darwinian expression of what has been identified as the modern Darwinian synthesis, whereas the application of Darwinism to sequences of social development has been more contentious. It is therefore important that we begin by clarifying the neo-Darwinian principles that have found application in the archaeology of human and cultural evolution before considering the extent to which those principles have themselves come under review.

Darwin provided a detailed argument as to how the reproduction of life could have resulted in the diversity of living things, rather than that diversity being the unchanging product of a single design. The Darwinian model requires the operation of two relatively autonomous processes in which one, natural selection, acts upon the other, heritable variability. In this model the direction of travel of an evolving lineage is determined by the process of natural selection that winnows out the traits deemed less successful from the wider diversity that is available. Life therefore throws up possibilities, while its direction is

decided by the forces of selection. Three things should be noted. First, Darwin did not know what mechanism carried heritable traits from one generation to the next. Second, natural selection needs to act upon a range of variability within a population, and yet natural selection might appear to reduce variability over time. Third, Darwin, perhaps unwisely, adopted the aphorism of “survival of the fittest” from Herbert Spencer, thus emphasizing competition for reproductive success between individuals. This renders as problematic the evolution of altruism and those cooperative behaviors that necessarily reduced the reproductive potential of some individuals.

In 1900, the experimental results that had been achieved nearly 50 years earlier by Gregor Mendel with his controlled cross-pollinating between plants of the pea family were rediscovered. These experiments demonstrated the particulate and statistically predictable inheritance of individual traits from one generation to the next, implying that such traits were carried by some singular, determinate factor: a unit of inheritance that the Danish botanist Wilhelm Johannsen named the gene. The general synthesis of Mendelian inheritance with Darwinian evolution resulted in a distinction being drawn between the phenotype, which is the physical form of the organism upon which natural selection acts, and the genotype, being the inherited material, the survival of which is consequential upon natural selection. The resulting dominance of the gene-centered view of life was provided with an object for its analysis when, in the 1950s, Francis Crick and James Watson, drawing upon the images of X-ray crystallography that had been prepared by Rosalind Franklin, established that two intertwined polymer strands of DNA, held together by the paired bonds formed between four kinds of nucleobases, were the basic structure that carried genetic information.

The idea that genes provide a blue-print for the design of an organism is still widely accepted in the popular imagination, and by the middle of the last century it had resulted in a strongly reductionist form of neo-Darwinism. Natural selection, acting upon the reproduction of

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

DOI: 10.1002/9781119188230.saseas0234

organisms with their relatively brief lifespans, was characterized as resulting in the ongoing and cross-generational survival of successful genetic lineages. This “gene’s eye” view of evolution was well expressed by Richard Dawkins who characterized organisms in the relatively passive role of “vehicles” that were built and that carried, and whose destiny was mainly determined by the more active genetic “replicators” (Dawkins 1976). From this perspective it seemed as if genes only existed to be replicated, while evolution traced the selective replication of successful genetic sequences. The necessary diversity upon which natural selection could act could now be provided for by the drift of new genetic material into a population and by the replication of genetic mutations, and the evolution of altruism was explained as the process of “inclusive fitness,” where the altruistic sacrifice of its reproductive potential by an individual organism was taken to increase the survival chances of the genetic replicators which that organism shared with its kin. In sexual reproduction, offspring inherit DNA from both parents, and the current ability to both map coded sequences of DNA and extract DNA from ancient material has meant that lines of transmitted biological inheritance can be traced through the long sequences of primate evolution and, to a more limited extent, across the histories of recent human populations. At the larger chronological scale this work has confirmed the evolutionary origin of modern humans (*Homo sapiens*) in Africa, demonstrated the evolutionary closeness of the relationship between *H. sapiens* and the African great apes, and clarified the biological distinction, along with some possible interbreeding, between Neanderthals and *H. sapiens*. It has also demonstrated that four populations belonging to the human genus *Homo* coexisted across Africa and Asia some 50–60 kya. Of these, only *H. sapiens* now survives. The complexity of biological inheritance is now indicated for more recent populations by the recovery of ancient DNA from skeletal remains. The matching of haplogroups demonstrates a European inheritance from south-western Asia in connection with the spread of agriculture and a northern and central European inheritance from the Eurasian Steppe associated with the development of late Neolithic single grave burial.

The Darwinian principle of evolution as a process of selective transmission, and the neo-Darwinian emphasis upon the selective transmission of genes, has been extended by the realization that other lines of heritable transmission might also submit to selection. Dawkins first raised this possibility with the idea that human life was structured by the inheritance of both biological genes and cultural “memes” (Dawkins 1976). These two lines of biological and cultural transmission provided the basis for dual inheritance theory (Richerson and Boyd 2005). If cultural inheritance is governed by the teaching and copying of behavior, where variability results from innovation and the drift of ideas and their mutation, and where selection may be due to various social demands but may otherwise be biologically neutral, then the Darwinian principle of descent with modification is still applicable to cultural systems of inheritance (Shennan 2002). As a consequence, archaeology has been able to map lineages of material cultural development as indicative of the ways various styles of cultural expression spread chronologically and geographically through human populations. Cultural evolution, with its emphasis upon the mutation and transmission of modular ideas (memes) that give rise to cultural traits, conforms to the neo-Darwinian model of evolution with its treatment of natural selection acting on particular unitary parts of the genotype (genes).

Biological evolution is witnessed by changes in a reproducing population, while populations are themselves defined through the growth and development of their individual members. Consequently, evolution should mean changes in the developmental characteristics of individuals. This explains the recent emphasis that has been placed upon the need to understand the complexity of developmental processes that affect the growth of individual organisms and that involve more than a genetic blue-print directing that individual’s development. Given that genes (or for that matter memes) do not actually do anything, the many developmental resources inherited by an individual and that extend well beyond DNA must include the contexts that enable inherited information to be acted upon. Recent moves towards a “post-Darwinian” model of evolution (Kull 1999) are therefore based upon the need to understand the evolution of developmental

systems (Oyama 2000). From the perspective of evolutionary development (sometimes referred to as “EvoDevo”), the content or meaning of an information source, such as DNA, is not contained in the material itself, but is assembled by the interpreting facilities that are contained, for example, in the cell. This approach has employed the theory of semiotics that was developed by the American philosopher C. S. Peirce (El-Hani, Queiroz, and Emmeche 2009). Peirce established semiosis as the processes in which an interpreter identifies a sign as standing for some object quality and responds as an interpretant to that identification. In biological terms, the living cell contains facilities that interpret segments of DNA as signs that specify some object of value to which the cell responds, as an interpretant, by replicating as cells that have a particular kind of function.

The treatment of life as a semiotic process (Hoffmeyer 2008) therefore questions attempts to distinguish between a biological determinism, as it has been applied to the agencies of the natural, living world, and a cultural indeterminism, as it has been applied to human agency. Instead, the processes of semiosis imply that the development of life in general can be treated as diverse processes of self-definition and self-making (Maturana and Varela 1980) that are made possible because biological systems identify and interpret available sources of information and exploit available sources of energy (metabolism) to sustain a particular niche of adaptation.

Understanding this process implies that life is, in general, conscious (Thompson 2007) and it situates the discipline of biology between the natural sciences and the humanities. Given that this is also the position that many commentators have assigned to archaeology, the implication might well be that we require a closer understanding between the two disciplines, and

where archaeology might be characterized as the historical study of human “biosocial becomings” (Ingold and Palsson 2013).

Experiment in Archaeology

MARTIN SCHMIDT

Niedersächsisches Landesmuseum Hannover,
Germany

Academic archaeology has long suffered from an inferiority complex in comparison to subjects such as history and anthropology. Acquiring data manually by digging in the dirt is sometimes not regarded as an intellectual activity or proper academic work. In consequence, archaeology has struggled to acquire a theoretical base. Experimental archaeology did not fit into this framework at all, as it is often done by amateurs, it needs practical skills, and the knowledge of craftsmen, and is again a manual activity. Only with the material turn in the humanities and the growing theoretical recognition of making (Ingold 2013) as a fundamental part of human existence has a general theoretical framework emerged that experimental archaeology can fit into. Experimental archaeology deals with both the materials and the materiality of the past.

Of course, there are different national traditions within the discipline (Reeves and Paardekooper 2014). In Germany and many other countries in Europe, archaeology meant first and foremost antiquarian research, and the function, use, and methods of production of the excavated artifacts were not of much interest. As archaeology was part of the humanities, experiments were not part of the epistemological background of the discipline, and were relegated to a few tinkerers or to outreach work. Early experimenters were thus often not professional archaeologists. The most prominent example is the German physician Ludwig Pfeiffer, who published in the year 1913 a groundbreaking ethnoarchaeological study on Stone Age technology.

Early archaeological experiments began in the seventeenth century. These early experiments investigated whether so-called thunderbolts could have been manufactured by humans, and

whether the black coloring of cinerary urns might have been caused by smoky wood fires, that is, firing in a reducing atmosphere. In the second half of the nineteenth century, ethnographic observations were increasingly employed (see ETHNOARCHAEOLOGY), but generally as direct analogies, without any consideration of social and cultural context.

The real boom in experimental archaeology only began in the 1960s. Thor Heyerdahl's ocean crossings fired the public imagination, but there were also carefully planned long-term experiments such as the Overton Down experimental earthwork. The two books of John Coles were very important in this context, and they have been translated into numerous languages. Nonetheless, some archaeologists were very critical of the epistemological value of an experimental approach, for example, Childe, Clark, and Movius (see Shimada 2005).

From the very beginning, experimental archaeology was linked to open air museums, and the fields of ancient technology, living history, and outreach. Therefore, activities such as learning a "prehistoric craft" or "public demonstrations" in museums have been sold under the label of experimental archaeology. In a wider perspective, all these activities fit the label of *making*, but with different aims: the better understanding of the archaeological record, learning "prehistoric techniques," replicating artifacts, or teaching students and the public. Experiments, experience, and education are all important aims, but there are different methods for achieving them; therefore, a clear distinction between these different types of making is of utmost methodological importance (Reynolds 1999). The lack of this distinction has led to confusion and has been detrimental to the development of experimental archaeology as an independent and well-founded discipline.

Experimental archaeology can be defined as the use of scientific experimental methods to answer archaeological questions. This covers a spectrum from knapping a simple flint flake to complex and long-term taphonomic experiments. Söhnke Ahrens (2014) has provided

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

an outstanding introduction to the subject of experiment in general. All experiments have to be replicable and take place under controlled conditions. There are numerous practical guides on how to conduct these archaeological experiments (Shimada 2005).

Peter Reynolds (1999) differentiated between:

- constructs and “reconstructions”;
- procedural and functional experiments;
- combinations of the three above;
- simulations; and
- experiments in technological innovation.

There is also a distinction between experiments in the field and in the laboratory. However, it is often impossible to clearly separate the two. In order to identify clearly defined variables that can then be investigated in systematic ways, it is often necessary to conduct numerous less well-controlled tests first. However, this is not really all that different from the procedure followed in the sciences.

In many areas of experimental archaeology, there is a broad overlap with archaeometry. Unfortunately, the latter often restricts its enquiries to composition and provenance. A very “sciency” type of experimental archaeology thus often leads to a lack of interesting research questions, especially if not enough attention has been paid to the archaeological context. However, there is a trend for a more integrated and theoretically informed archaeological science (Martínón-Torres and Killick 2014), which should lead to a more fruitful cooperation between the disciplines. This hinges, however, on the definition of clearer research questions. As Reynolds already pointed out in 1999, there is a need for a matching of research questions, methods used, and the design of the experiment.

It is also necessary to consider which questions can realistically be addressed by archaeological experiments. For example, the time spent on any specific task is mainly dependent on the experience and manual skill of the experimenter. Measuring time is only useful if the experimenter is very experienced and familiar with the workflow, tools, materials, and technologies. While the characteristics of scientific experiments have been clearly defined, archaeology cannot always

follow these prescriptions, because only very rarely can all the parameters be clearly defined. In this context, it is important to point out the importance of tacit knowledge.

The question of appropriate recording techniques is also worth consideration. An experienced smith can judge the temperature of the fire by the color of the flames, and a thermocouple may not be necessary. If a smith is unable to do this, he or she may actually not be the best person to conduct the experiment in the first place. Identifying key factors should thus precede the amassing of data of doubtful relevance. There is also the need to reflect on the specific requirements and (im)possibilities of archaeological experiments in the context of the humanities (Ahrens 2014; Wind 2001). There are numerous approaches, for example, that can be arrived at by stressing the fruitful and methodologically complementary connections to ethnoarchaeology. A better integration and a reappraisal of experimental archaeology in the context of the humanities has long been called for, and would be beneficial for archaeology in general and could lead to new research questions, beyond a limited focus on technology. Recently, the terms “dissociation from the artefact,” “intangible heritage,” “emotion,” “humanistic scholarship,” “phenomenology,” and related theoretical approaches (Petersson and Narmo 2011) have appeared in the discussion.

The methodological and theoretical basis of experimental archaeology is still poorly developed, which often leads to a simplistic positivist approach. Only a few discussions have focused on the development of a theory of experimental archaeology (Lammers-Keijsers 2005). This inherent positivism also explains why experimental archaeology thrived in the climate of processual archaeology. As yet, there are very few attempts at a postprocessual experimental archaeology, and these have mainly been in the field of phenomenology. A methodological and theoretical handbook of experimental archaeology has yet to be written.

In the end, an experiment only proves what was or was not possible. This does not, however, invalidate the approach. Experimental archaeology can be seen as a hermeneutic spiral. In a framework of a well-defined methodology and constant feedback with archaeological finds and

Figure 1 Circle of experimental research.

features, historical reality can be more and more closely approximated (Figure 1).

Present-day criticism of experimental archaeology is mainly directed at badly defined research questions, lack of practical experience and technical skills on the part of the experimenters, and poorly prepared and poorly conducted experiments. Increasingly, experimenters lack the practical skills required, and it would often be sensible to publish results as test or pilot studies, rather than experiments proper. Amazingly, cooperation with skilled and experienced craftpersons is rarely sought. Many historical crafts are dying out, or becoming very rare. However, there are now some archaeotechnicians who both are skilled craftpersons and have a solid academic background in archaeology. But there is no formal education or chartered body for the subject, so any progress here depends entirely on personal initiative.

Also, the breadth of modern knowledge can be misleading. Many modern flint knappers, for example, command a much wider repertoire of techniques than was present at any point of time in prehistory. So this is also a crucial point for conducting archaeological experiments. A lack of sufficient technical support and infrastructure is holding back the development of the discipline. Suitable laboratory space is often not available. For all experiments, the analytical tools and

apparatus have to be chosen according to suitable objective and subjective criteria. In addition, the experiment has to be designed in a way that does not advantage any of the possible outcomes. Furthermore, it has to be considered how far the results have been influenced by the choice of method. Observation and interpretation have to be kept separate. By definition, all experiments have to be replicable and should be repeated several times. They can then be tested under different circumstances. This also helps the experimenter to hone his or her skills.

The results then need to be published in a correct and comprehensible fashion (<http://journal.exarc.net/eurorea-2-2005/ea/how-publish-experimental-archaeology>). Unfortunately, “failed” experiments, that is, experiments that rejected rather than supported a given theory, are rarely published, although they may have produced a good deal of information which might have helped to inform future research. In contrast, experiments that failed through lack of proper equipment or methodology are published far too often.

A critical attitude to the work that has been done is indispensable, however. A blind acceptance of received wisdom prevents the perception of truth, or, rather, the assessment of correctness. The biggest problems are still diffuse and imprecise research questions and an often

total ignorance of current and past research. In particular, a lack of linguistic skills leads to the formation of regional research traditions which totally ignore results that have been obtained in other countries. This is especially true for Anglo-American archaeology. Thus, the wheel is frequently reinvented without any progress in research methods or results.

Presently, there are two main camps in experimental archaeology. On the one hand, there are the adherents of a strictly scientific methodology (most prominent Reynolds 1999). They demand a strict separation from other subjects, such as the acquisition of practical technical experience, trying out techniques, demonstrations for the public, and living history, as well as museum education and exhibits in open air museums. Open air museums are generally understood to be excellent venues for experimental archaeology, but it is often ignored that experimental archaeology and the general public do not mix well. Therefore Peter Reynolds in his famous Butser Ancient Farm strictly separated public and experimental areas. Others claim that experimental archaeology can (or needs to) be mixed with other approaches like public archaeology, open air museums, living history, and museum education, because they are somehow fundamentally connected. Furthermore, the importance of the popularization of archaeology in terms of both politics and public expenditure is an argument that is widely supported.

These two approaches are equally valid, but a naive mixture discredits both. It may be that the time has come to find a new and overarching definition for experimental archaeology, united under the rubric of making. But it is of utmost importance to clarify preconditions and aims. Today, the number of publications on experimental archaeology and archaeological experiments is so extensive that it is almost impossible to keep track of the literature. Repositories and databases (e.g., EXARC Experimental Archaeology Collection: <http://core.tdar.org/collection/60199/exarc-experimental-archaeology-collection>) would be invaluable in accessing information about previous investigations, and planning worthwhile future work. In addition, in many countries an institutional base for experimental archaeology is lacking, as well as laboratories, university institutes, and other research institutions.

A broad spectrum of experiments has been undertaken by archaeologists. There is insufficient space to discuss them in detail here, and the reader is referred to the literature listed below. Archaeological experimentation is increasingly complex in character. While it was formerly sufficient to reproduce an artifact such as a flint dagger, nowadays the distribution and character of the debitage produced in the process will be studied, in order to understand finds distributions on archaeological sites and their subsequent transformation. The study may be taken further with an investigation of possible uses, and the resulting use wear, as well as breakage and the character of deposition. Today, the simple replication of an artifact would scarcely rate as an experiment any more.

While “making” is gaining popularity as a framework for investigation, and will hopefully become part of mainstream archaeological education, experimental archaeology is honing its definition as a distinct subfield of archaeological research, with a well-defined methodology and an ever-increasing range of techniques. Nonetheless, experimental archaeology is an invaluable method which, where it has been conducted properly, has achieved a great deal for our understanding of the past.

Gender and Sexuality

ROSEMARY A. JOYCE

University of California, Berkeley, USA

From its beginning as a modern discipline, archaeologists have applied the terms male and female to some persons represented in archaeological sites by skeletal remains, images, or tools used in specific activities. Serious consideration of how biological characteristics indexed by the terms male and female were linked to social identities and sexual practices, however, did not develop until the late twentieth century. Some of the impetus then came from feminist science studies (see SCIENCE AND FEMINISM). However, not all of the researchers developing this new archaeology of gender were identified as feminist. A shift in composition of the field itself took place, with many women entering the discipline undertaking research on women's roles in the past, often even as students.

Today, archaeologists exploring gender and sexuality use the same methods and evidence as other archaeologists. There is no particular form of fieldwork or laboratory work that defines archaeology of gender and sexuality. Data derived from the study of human skeletal remains, figural representation, burials, and households are common, but not the only sources employed. At the leading edge of archaeology of gender and sexuality, bioarchaeologists, trained to study human skeletal remains with archaeological questions in mind, are undertaking sophisticated research that questions the very nature of the sexes, and archaeologists drawing on queer theory interrogate the terms taken for granted in the first generations of archaeology of gender.

Historical development of archaeology of gender and sex

Sex determination, a long established archaeological approach to gender and sexuality, is an

integral part of bioarchaeology (see BIOARCHAEOLOGY; ESTIMATING SKELETAL SEX: CRANIAL AND PELVIC MORPHOLOGY; and ESTIMATING SKELETAL SEX: METRICS). Even when the production of dichotomous sexual categories is being contested, archaeologists often treat biological difference as likely to have shaped differences in lived experiences. The study of figural representations, ranging from monumental sculpture to small ceramic figurines, has as long a history of being employed in the identification of people of different genders and interpretation of their experiences. Analysis of burials has also long included the assignment of gender identity to buried individuals. Sometimes this was based on bioarchaeological analysis, but often it involved inference from materials included with the body, such as personal ornaments or tools deemed appropriate to certain activities assigned to one gender, relying on stereotypes.

These approaches long predate the late-twentieth-century development of a recognizable archaeology of gender and sexuality. Each identifies dichotomous sexes or genders through an often unreflective association with unique activities, objects, or roles. While these approaches continue in use in archaeology today, they have been challenged. Beginning in the 1960s, more theorized attention to the presumed sex and gender of specific people who shaped archaeological sites grew out of a new focus on household archaeology (Wilk and Rathje 1982).

Household archaeology occupies a distinct, if seldom acknowledged, position in the emergence of explicit archaeological research on gender and sexuality. Household archaeology was part of an agenda of systematic investigation of socioeconomic structures of settlements identified in regional scale projects. Archaeologists, sometimes explicitly drawing on cybernetic systems theory, treated regional social and economic relations as forming connections among subsystems that together produced continuation of the system, including buffering and counteracting feedback that would tend to disrupt a regional-scale system.

DOI: 10.1002/9781119188230.saseas0252

Systems theory approaches to regional-scale social and economic organization did not treat aspects of human difference as in need of formal modeling, so there was no archaeology of gender in the analysis of society as system. However, these models did single out for special attention minimal units of production and consumption. This level of the system was identified with the ethnographically and historically observable household, itself a highly variable social science construct (Wilk and Rathje 1982). Household archaeology formally addressed the unpacking of households that in systems theory were treated as complex wholes not subject to analysis ("black boxes"). The original purpose of household archaeology was to understand through historical research the variability of elements in this fundamental unit of socioeconomic organization. Household archaeology relied heavily on analogical arguments justified by surveys of ethnographic and historical case studies. These analogical arguments inevitably required attention to differences along lines of age, status, and sex among the people making up households.

It is thus unsurprising that one of the most influential early contributions to an archaeology of gender started as a conference on the role of women in production (Conkey and Gero 1991). The contributions to this volume examined women's roles in face-to-face social relations from the deep time of Palaeolithic Europe to the historic Inka and Aztec states of the sixteenth century. Contributors argued that residues from food preparation, debitage from production of expedient stone tools made on the spot for specific tasks, and workshop-scale pottery crafting all needed to be examined to identify the roles of women, often previously denied or ignored. Participants proposed novel arguments giving women roles in the emergence of plant cultivation, the social organization of nonstate societies, and transformations in the economic systems of states undergoing colonization.

Initially, archaeology of gender was practiced comfortably within dominant positivist research approaches. With the emergence of archaeology of gender as a specialization in the 1980s and 1990s, marked by numerous conferences, edited volumes, and even entire journals, it became evident that archaeologists were not necessarily

employing unified definitions of terms, or exploring agreed upon research questions. Some work was oriented to create a larger body of data about the historical position and actions of women: an archaeology of women. Other work was aimed at defining theories of gender as an aspect of historical social, political, and economic relations, often informed by contemporary feminist thought from outside archaeology (see *SCIENCE AND FEMINISM*): feminist archaeology. Less common was work directed at interrogating the assumptions that archaeologists used when thinking about the past, and identifying places where assumptions about gender were embedded in normative archaeology: what we could call an archaeology of gender.

Today, a spectrum of research positions exists in archaeology of gender and sexuality, from perspectives inspired by queer theory that question the use of any categories of sex or gender, to continued reliance on biological markers used to create dichotomous male and female categories taken as fundamental to binary social gender relations. Where archaeologists engage with feminist science studies (see *SCIENCE AND FEMINISM*), they contribute to discussion of the multiplicity of sexual categories that can be based on different biological markers. When archaeologists draw on work in gender and women's studies, they argue that social identities must be viewed as intersections of different aspects of individual experience, requiring consideration of racial, ethnic, and socioeconomic status along with sex or gender. Those archaeologists who build on insights from queer theory see archaeology as a source of evidence that sex or gender categories are not natural outcomes of biology, but rather are products of specific culture histories.

The most promising contemporary research goes beyond identification of women or even of people of multiple genders in specific past situations. Bioarchaeologists have taken leading roles in questioning the effects of dividing human populations into two subgroups for analysis (see *BIOARCHAEOLOGY; ESTIMATING SKELETAL SEX: CRANIAL AND PELVIC MORPHOLOGY*; and *ESTIMATING SKELETAL SEX: METRICS*). Archaeologists drawing on queer theory have begun to employ the rich reservoir of case studies assembled through positivist research to show

how archaeology of gender and sexuality contributes to broader projects of denaturalizing the representation of specific forms of human social organization as inherent aspects of human existence (Geller 2009; Ghisleni, Jordan, and Fiocoprile 2016; Weismantel 2013). Contemporary approaches make archaeology of gender and sexuality relevant to broader social sciences and even social policy.

From an archaeology of women to archaeology of gender and sexuality

Documentation of women in prehistory was the first product of archaeology of gender as it emerged in the 1980s. New studies often used recent ethnographic observations, or even undertook new ethnographic research to expand the basis for answering such questions as to who hunted, who butchered, who prepared and tended fields or raised animals. Researchers proposed that women had greater roles in making the tools used in everyday life, and in domesticating plants and animals, than traditionally assumed.

A subgroup of studies of women in the past pursued the identification of women in positions of power, previously overlooked or explained as exceptional. Some studies drew on less well known historical traditions, for example, power possible in contexts open only to women, like celibate communities of nuns (Gilchrist 1994). Others reconsidered the minimization of women's power in societies where some historical women had long been recognized but interpreted as subordinated by men of the ruling class, an approach taken to the Classic Maya by an international group of researchers, many explicitly feminist (Joyce 2001).

While sometimes derisively characterized as "add women and stir" research, this work, whether explicitly or not, involved a theoretical shift from previous archaeological practice. In place of a singular, normative human subject (by default male), archaeologists had to specify the social position of the actors whose traces they were interpreting.

There were, however, problems with the simple approach to looking for women in the past (Joyce 2008). These are exemplified by proposals

like those that women had major roles in the initiation of plant domestication and the creation of the first fired clay vessels. Arguments like these usually proceeded from the assumption that women in the past would have been responsible for domestic tasks, such as preparation of meals and tending of fires, giving them a closer relationship to the plants and materials altered in significant moments of technological change. This assumption can be recognized as a kind of strategic essentialism, countering a tendency to obscure women's undeniable presence in the past by demanding some kind of special "signature," a unique artifactual pattern in an assemblage that would be signifying the sex of the person making or using it. Strategic essentialism stabilizes cultural interpretation long enough to allow proposals that a subordinated or obscured person was active, at the price of subscribing to a generic form of identification. Yet generic forms of identity employed in strategic essentialisms are often held to be resistant to change, or even natural and in-born, raising a new set of problems.

The essentialism at work in archaeology of gender was often supported by a historical argument: that human societies have always had a division of labor based on sex in which women's roles were partly determined by reproductive biology. Archaeologists dealing with the long history of human evolution argued that due to differential demands of pregnancy and infant care, and the inability of males to know that they are genetically related to the children born to women, humans would have had a long evolutionary history of female childcare, including the first provision of food to others. This argument relied on a close linkage between a biological sex and social gender role that can be seen in retrospect as unfortunately reductive, since it left no role for the unpaired female (or male), or the female without offspring, and positioned forms of sexuality that were not male–female pairs as abnormal or unnatural.

It was issues like these that led archaeologists to begin to question basic assumptions about gender, producing a critical archaeology of gender. Archaeologists working in societies with a high degree of socioeconomic variation, especially those informed by Marxist analysis, suggested that gender needed to be understood in articulation with socioeconomic status. For

these archaeologists, the archaeology of queens was less about gender, and more about class structure and power.

Archaeologists inspired by the work of queer theorists, especially Judith Butler, questioned the proposition that biological sex was the ground for the development of social gender. Butler, and archaeologists employing related analyses, saw the separation of sex and gender in discourse as misleading, producing an effect of naturalness around what they argued was always a social experience of being. The corporeal aspects of being that archaeologists called sex were not precultural, and they did not provide solid grounding on which cultural performances that could be called gender could be formulated (Joyce 2001). For these scholars, it did not matter if archaeologists acknowledged that there was no deterministic correspondence of sex and gender, no universal female experience. The flaw was already there in treating sex and gender as two different things, one more fundamental than the other.

An important body of archaeological work built on questioning the sex/gender equation by examining the existence of multiple or alternative ("third") genders. Inspired by ethnographic and historical sources, archaeologists working in the Americas in particular noted that descendant communities of the societies whose remains archaeologists explored often recognized three or more social genders (Joyce 2008). Less commonly, archaeologists drew on work by feminist biologists arguing that even biological sex was not a dichotomy, whether it was assessed based on chromosomes or reproductive organs (Geller 2009).

The way discourses and practices of sex and gender formed became the focus of many archaeologists who followed this critical path. Nothing could be taken as natural anymore. Archaeologists investigating sex or gender relations (now often interchangeable, or even used as a compound term sex/gender) needed to account for the social and economic organization through which categories of persons could have emerged in the past in action or performance, or as objects of social constraints or freedoms. Historical archaeologists, working in situations where legible documentary records are one of the bodies of material available, were central

to the development of critical approaches to an archaeology of gender (e.g., Gilchrist 1994). Yet archaeologists working on even very early societies for which forms of data are less rich also were able to undertake analyses that asked how genders manifest or become recognizable, and what forms gendered social relations might have taken, without presuming the presence of a simple dichotomy between male and female linked to bodily differences.

At the same time that analyses of the social determination of gender developed out of critical archaeologies of gender, other archaeologists continued to be concerned with how the experiences of people are shaped by whatever sex or gender relations exist in specific historical circumstances, with special attention to the material dimensions of experience that provide the focus of archaeological methods and arguments. This focus on experience often involved consideration of embodiment separate from gender (see *BODIES AND EMBODIMENT* and *EMBODIMENT*). In the late 1990s, it gave rise to novel work that went beyond the parameters of archaeologies of sex or gender to consider sexuality (Schmidt and Voss 2000). The archaeologists who engaged with questions of sexuality might share an interest in social regulation with archaeologists of sex or gender, but they also were concerned with experiences of desire and sexual practices. Rather than simply cataloguing additional genders, they asked what kinds of sexual relations were practiced where genders beyond male and female were recognized. Ultimately, archaeology of sexuality opened up the field to queer theory, which continues to be a major source of advances in the archaeology of gender and sexuality today.

Current emphases and future directions

Archaeology of gender continues to include much work based on the assumption that there is a biological dichotomy of male and female which different societies recognized with different genders, sometimes more than two. This work continues to add empirical case studies of women's and men's roles in past societies. Contemporary archaeology of gender and

sexuality grounded in queer theory goes further, and includes work intended to disrupt any such assumptions. Researches engaging with queer theory note that most archaeology continues to be implicitly heteronormative, assuming that in all past societies the majority of people were engaged in male–female sexual relations (Geller 2009; Joyce 2008; Weismantel 2013). Even research that seeks to trouble archaeology’s heteronormativity can sometimes be limited to consideration of “alternative” sexual cultures, which may leave in place the assumption of heteronormativity.

The contradiction between archaeological work based on assuming a determinative relation between biological sex and social gender, and critical work rooted in queer theory that rejects the use of such terms as universals, can lead to exchanges in which archaeologists on one side assert that dichotomous sex/gender systems are natural (and thus universal) because they are “necessary” for reproduction, and those on the other side argue that biologies are always recognized in terms of social categories of what is taken as natural (and thus acceptable). Contemporary work, however, goes beyond these “binary binds” (Ghisleni, Jordan, and Fiocoprile 2016). In contemporary archaeology of gender, gender or sex is treated as historically contingent, as likely to be fluid as fixed. Contemporary work may treat sex or gender as a spectrum, not seeking to identify any specific number of genders or sexes.

This does not result in inattention to ways human difference has been mobilized in unequal relations of power, or a lack of attention to recognizing people in the past who might have systematically been denied access to power due to their sex or gender. While maintaining connections between bodily experience, difference, and sex and gender, contemporary work has moved away from the centrality of reproduction that

characterized earlier archaeology. Biological sex and gender are no longer taken as universally central to human identity. Even when they are recognizably important, biological difference or cultural experiences that archaeologists recognize as sex, gender, or sex/gender are now routinely examined in terms of the intersection of race, ethnicity, age, and social status.

History and Sociology of Science

GÉRALDINE DELLEY

University of Neuchâtel, Switzerland

SÉBASTIEN PLUTNIAK

École française de Rome, Italy

Archaeology and sciences or archaeology as science?

From the late nineteenth to the early twentieth century, human and natural sciences were gradually reorganized into institutionalized forms. The diversification of research trends in archaeology, a trend also observed in other sciences, led to a number of ways to refer to the natural sciences, which ranged from using them as a model of scientificity to defining the difference between them and the human sciences. Local histories of scientific institutions, research traditions, and political and personal choices alike influenced the position of archaeology within the scientific field—a position that could be closer to or more distant from the human and natural sciences. The case of prehistoric archaeology highlights this crossing over of branches in the classification of sciences. The development of prehistory as a scientific practice in the second half of the nineteenth century relied on a wide range of approaches, including ethnography, history, physical anthropology, paleontology, geology, and botany, from which prehistory borrowed methodological and conceptual tools. In the nineteenth century, archaeology (see *ARCHAEOLOGY*) and prehistoric archaeology were part of a large research field that encompassed geography, physical anthropology, linguistics, and ethnography and aimed to describe and understand human history from natural and cultural perspectives (Blanckaert 2000). Consequently there is an intrinsic relationship between *archaeology* and *science*: the aim of producing archaeological

knowledge is *in itself* a scientific project, and it is preferable to talk about the relationships between archaeology and other sciences.

The term “archaeosciences” is loaded with the same content: if a part of archaeological practice is scientific (the “archaeosciences”; see *ARCHAEOLOGICAL SCIENCES*), what about the other part? The role of historians and sociologists of science is not to find the best solution to this problem, but rather to investigate the variations in the definitions of these terms. An important issue is to identify the relationship (in terms of epistemic and social dimensions) between archaeological practices and practices in the sciences applied to archaeology—in other words, to explore the diachronic and synchronic variations in the ways archaeology has been grounded as a scientific enterprise and the controversies surrounding this topic. Indeed, the concept of archaeoscience has its own history and is closely related to the concept of archaeometry (see *ARCHAEOMETRY*).

A brief examination of the evolution of the latter can clarify the relationship between archaeology and other sciences. It is important to understand the meaning of *-metry* in archaeometry. The term started to become popular in the 1960s, and in 1961 the first “Symposium on Archaeometry” was held in London; it was an annual meeting that focused on the applications of physical science in archaeology. The growth of archaeometry increased rapidly in the mid-1970s. From 1975 onward, the location of the symposium changed every year; the symposium itself became international and renamed “International Symposium on Archaeometry and Archaeological Prospection.” This internationalization was also reflected in the creation of the *PACT* group in 1976, by the Council of Europe. This group was defined as a European study group dedicated to the study of physical, chemical, biological, and mathematical techniques applied to archaeology. From 1977 on, this group published its own journal, the eponymous *PACT*; at the same time, in 1976 the *Groupe des méthodes physiques et chimiques de l'archéologie* (GMPCA) was founded in France in 1976 and started issuing its own journal,

Revue d'archéométrie, one year later. These three cases illustrate different definitions of archaeometry: in the UK symposia and in the French GMPCA, mathematics was included only insofar as it provided methods to process the results of physical and chemical measurements; on the contrary, in the European PACT group, mathematics was an integral part of the group's definition.

The concept of measurement is relevant to the measurement of abstract properties in mathematical objects and of concrete properties in physical objects. From the 1970s onward, however, archaeometry was concerned mainly with the measurement of concrete properties; it excluded mathematics and restricted itself to physical and chemical procedures designed to investigate archaeological facts. This evolution was also related to the professionalization of archaeology, the growth of archaeometry as a specialized field, and the redefinition of the relationships between archaeologists, mathematicians, physicists, and chemists. The extensive scope and multidisciplinary nature of archaeometry and of the archaeosciences illustrate the inadequacy of an analysis based only on a normative classification of the sciences and the relevance of a sociohistorical inquiry on this issue.

The first section of this entry focuses on the different approaches taken by authors who assess the relationship between archaeology and other sciences from social and historical perspectives, and on the evolution of these approaches. The evolution of these authors' aims is also examined. The second section focuses on a long-term perspective. Since the nineteenth century, archaeological research has integrated a range of aims, facts, and procedures borrowed from or shared with other scientific disciplines.

Scientific transfers and applications in archaeology: an overview of social and historical approaches

During the twentieth and twenty-first centuries, the position that authors occupied in their discipline and the nature of their work on the history of the relationship between archaeology and other sciences can be classified into three main categories. A first group is formed by internalists:

archaeologists who construct the history of their own discipline and practices, and aim to advance archaeological knowledge. The second group is formed by archaeologists who are concerned with the history of their discipline as a social practice (see *SCIENTIFIC PRACTICE*). The third group consists of externalists: historical and sociological analyses of the relationships between archaeology and other sciences are produced by historians, sociologists, or ethnologists positioned outside the field of archaeology. They aim to advance the knowledge of general phenomena related to past and present activities based on the case of archaeology.

Progress in archaeology: archaeology's relationships with other sciences

From the first decades of the twentieth century to the present day, many archaeologists have published reviews or methodological textbooks that aim to describe the diversity of tools available from the natural and formal sciences, as well as their limitations in archaeology. These contributions, assessing the relationship between archaeology and other sciences, aimed to strengthen the archaeological discipline and to support the research of archaeologists. In addition, they were conceived as a means of exposing the progress of the discipline, since they coincided with the first attempts at professionalizing prehistory (in the 1920s) and with the development of technical tools in physics, chemistry (see *CHEMISTRY IN ARCHAEOLOGY*), and isotope (see *ISOTOPES*) research (in the 1950s). An emblematic contribution is Annette Laming's book *The Discovery of the Past: Recent Progress and Techniques in Prehistory and Archaeology* (published in French; see Laming-Emperaire 1952).

Archaeologists examining their discipline as sociologists or historians

Since the 1990s, the relationship between archaeology and other sciences has been investigated by archaeologists influenced by or aware of approaches developed in cultural and social history and in the history of science. Examining the institutions, the actors, and their practices, these authors have tackled the relationship between

archaeology and other sciences within the context of formation and development of archaeology as a scientific discipline (Hurel and Coye 2011; Kaeser 2011). More recently, this relationship has been approached from the point of view of the development of specific tools and methods (e.g., 14C dating, dendrochronology, fluorine) that involve archaeology and natural and formal sciences, in a context of strong disciplinary affirmation (Delley 2015). Such researches focus on the behavior of the scientists and assess their actions in complex social interactions (e.g., power relations between disciplines and institutions, the role of politics in science, the relation between science and the army, medicine, culture). The use of archives, the contextualization of observations, as well as the historicization of the categories commonly used in archaeology (e.g., dating, modernity, interdisciplinarity, amateur, professional: Plutniak 2017) are constitutive of this approach, which is recognized either as a component of archaeology or as a part of the history of science.

Archaeology as a case study for social studies of science

Since the 1940s and following the pioneering work of Robert Merton, social and historical studies of science grew in number and were empirical investigations of various disciplines. Until the present day, however, archaeology has rarely been investigated by sociologists or science historians. In fact, social studies of sciences have focused mainly on natural, formal, and experimental sciences; one explanation is that archaeology is a newer discipline by comparison to physics, mathematics, or physiology. Nevertheless, there are some studies that have addressed sociological questions regarding the relationship between archaeology and other sciences. An example is the sociology of expertise developed in Bessy, Chateauraynaud, and Lagrange (1993). This work investigates the case of Glozel, an alleged forgery site, and shows how arguments grounded on the use of radiocarbon (see RADIOCARBON CALIBRATION AND AGE ESTIMATION) and thermoluminescence (see DATING CERAMICS AND LUMINESCENCE) can be controversial. The sociolinguistic approach

is another example (Goodwin 2000). Dealing with ethnomethodological questions related to the role of vision (or visual experience) in the analysis of situated practices, Goodwin analyzed how archaeologists decide the description and colors of a stratigraphy. During the 1990s, the influence of postprocessual archaeology and its particular relation to ethnography and reflexivity (see SYMMETRICAL ARCHAEOLOGY) blurred the frontier between archaeologists analyzing their own discipline and sociologists or historians examining archaeology as a case study. An example is the collective book on the ethnography of archaeology (see ETHNOGRAPHY AND QUALITATIVE METHODS IN THE FIELD) edited by Edgeworth, an archaeologist, which collects papers from archaeologists, sociologists, curators and linguists (Edgeworth 2006).

The relationships between archaeology and other sciences: examining time

The relationship between archaeology and other sciences encompasses a wide range of scientific practices and relationship modes, for example transfer of concepts (by analogy or metaphor), methods (devices or skills), or knowledge aims. To give a short but broad example, this section focuses on the case of examining time (see TIME AND TEMPORALITY) by distinguishing three main categories of scientific methods of inquiry: observing (the effects of time), measuring (the effects of time), and computing (temporal data).

Observing the effects of time

Since the second half of the nineteenth century, observing the effect of time has been a central question in prehistory. Archaeologists expected the natural and formal sciences to devise methods to resolve this issue, in addition to the usual tools of classification (see ARCHAEOLOGICAL CLASSIFICATION) of artifacts and stratigraphy. In the early nineteenth century, the paleontologist Georges Cuvier and the mineralogist Alexandre Brongniart defined a methodological tool where faunal characterizations were used to establish

a relative chronology between different stratigraphical layers. A few decades later, a scheme for recognizing and characterizing the successive stages of the development of material culture was established by Christian Jürgensen Thomsen and Jens Jakob Asmussen Worsaae on the basis of the collections stored at the National Museum of Copenhagen. Named the “three-age system,” this conceptual tool relies on the morphological and technological analysis of archaeological material. The composition of this material (stone, bronze, or iron) establishes a division of time. In the 1840s the demonstration of the antiquity of “man” by Jacques Boucher de Perthes was built on naturalist and cultural principles involving paleontological, geological, anthropological, and cultural observations (see MATERIAL CULTURE) and established the first elements of what would become the scientific practice called prehistory. At the same time, in Denmark, a commission of experts composed of archaeologists and naturalists explored the famous kitchen midden (*kjoekkenmoedding*), whose chronological attribution was highly problematic. Around the 1870s, Gabriel de Mortillet used in his classification of prehistoric industries paleontological stratigraphy and the “three-age system.” Naturalist and cultural conceptions are built using evolution theory, which is based on geological and paleontological evidence applied to the morphological classification of human artifacts (Hurel and Coye 2011).

Since the late nineteenth century, wetland zones—marshes, bogs, and lakeshores where organic remains are particularly well preserved—have been locations of intense exchanges between naturalists and archaeologists. During the first half of the twentieth century, these collaborations took institutionalized forms with the creation of laboratories and institutes in Tübingen, Groningen, and Basel that aimed at including botany and palynology—besides sedimentology, paleontology, and material culture—in the practice of archaeology. The history of vegetation and climate (see CLIMATE CHANGE AND DATING), combined with the fine analysis of stratigraphies and artifact typologies, stems from the same preoccupation of observing the effect of time from a natural and cultural perspective.

Measuring the effects of time

The introduction of measurement in archaeology was an important methodological and epistemological step (see MEASUREMENT THEORY); furthermore, it also divided actors according to whether they could perform the method in question or not. These measurements concerned mainly the properties of cultural artifacts and organic and physical facts to the extent that they could reveal the effects of time.

A first case is the measurement of cultural assemblage properties. An example is the early development in seriation (see SERIATION) methods, introduced by Flinders Petrie in the late nineteenth century. Petrie also authored one of the first extensive applications of mathematics to archaeological facts in his book *Inductive Metrology*, published in 1877. Seriation methods consider a set of objects and measure the properties of each (for instance types of potteries). The variations observed in the targeted set lead the observer to infer the relative chronology of these objects. American archaeologists largely adopted and improved statistic-based seriation methods (see DESCRIPTIVE STATISTICS), notably in the work done in the 1910s in the Pueblo and Zuni regions by researchers such as Alfred Kidder, Alfred Louis Kroeber, and Clark Wissler, who integrated these methods within an evolutionary (see EVOLUTIONARY THEORIES) framework (see Lyman and O’Brien 2006).

Dendrochronology, which was introduced into Europe by Ebba Hult de Geer and Bruno Huber during the 1930s and 1940s, in botany (see CHARCOAL AND WOOD ANALYSIS), is at the frontier of observing the effect of time and measuring it. Dendrochronological curves can be built, and thus historical sites dated, by comparing and correlating the patterns of tree rings. The use of this method in dating prehistoric settlements was limited to establishing (although very precisely) relative chronologies until the 1980s.

Since the 1950s, radiocarbon dating has been considered, in textbooks on method, the emblematic example of a collaboration between archaeology and other sciences. This tool, developed shortly after World War II, determines the age of an object by measuring its radioactive decay. Analyses are performed in physical laboratories disconnected from the archaeological milieu. In

addition, the tool was quickly presented as being “under control” by laboratories, which expected a direct correlation between the ^{14}C decay curve and the calendar time curve. This assumption relied on the false hypothesis that the production of ^{14}C was constant through time. Statistical and computational methods of calibration (see RADIOCARBON CALIBRATION AND AGE ESTIMATION) were developed to solve this problem of the fluctuating ^{14}C production in the atmosphere.

Time computation

During the second half of the twentieth century electronic computers became more powerful. This advancement led to redefinitions of previous methods: the research problems might have been the same, but the methods used to solve them radically changed, as computational complexity became less of a limitation (see COMPUTER APPLICATIONS IN ARCHAEOLOGY). The main difference was that calculations were not made on the observed properties of archaeological facts, but directly on calendar data integrated into an abstract statistical time model. A shift occurred from dealing with representations of temporal effects to dealing with representations of time, which allowed for the integration of multiple dating sources in the same formal framework.

Regarding the development of dendrochronology in Europe, where climatic signals are weaker than in southwest America (where the tool was first developed by Andrew Ellicott Douglass), local dendrochronological curves can be inserted in a long referential curve, which connects the present day to prehistoric times and provides archaeologists with an absolute dating tool that necessitates the use of statistic computations. Physicians and statisticians developed Bayesian (see BAYESIAN STATISTICS) frameworks that allowed the calibration of unique datings and the integration and correlation of multiple dating sources (radiocarbon, dendrochronology, thermoluminescence). From the 1970s on, an important chronometer was developed on the basis of ancient DNA (see GENETICS: ANCIENT and GENOMICS: ANCIENT) and of the known mutation rate of biological molecules. The “molecular clock” hypothesis and method offered

a new way to estimate time in archaeology. Both DNA sequencing (see DNA: NEXT GENERATION SEQUENCING) and the calibration of the relative duration provided by the molecular clock rely on computational techniques.

In fact, the difference between observing and measuring the effects of time on the one hand and analyzing temporal data on the other is not only a matter of methods or concepts. The introduction of new methods to investigate time in archaeology also redesigned the organization and practices of archaeology, modified its boundaries, defined new powers and relationships between archaeologists and specialists in other disciplines, and changed the image of archaeology in society. Archaeosciences and archaeometry have for instance connected archaeology with the iconic place of modern science: the laboratory (Delley 2015). These aspects are empirically investigated by social scientists and historians.

Human Lives and Deaths

LIV NILSSON STUTZ

Linnaeus University, Sweden

Positioning the problem of a transdisciplinary archaeology

Archaeology provides multiple pathways from fragmented remains to reconstructed human lives and deaths in the past. These pathways require not only sound empirical grounding and archaeological evidence, but also archaeological and social theory broadly defined, thus tying together the natural sciences, the social sciences, and the humanities. The combination of solid data, sophisticated methods, and informed theoretical interpretation has driven our insights into past lives forward toward new insights and questions over recent decades. The current rise of scientific archaeology has in many ways contributed to increasing cross-pollination within the field, and to some degree dismantled the intradisciplinary conflict that arguably characterized archaeology in the 1990s. But as archaeologists become increasingly specialized, we must remain vigilant to not undermine this growing transdisciplinarity. To avoid a rift between the natural sciences, the social sciences, and the humanities within archaeology, it is imperative that we not only use each other's results, but also continue to build the cross-disciplinary literacy and connections, as new approaches, methods, and paradigms develop in these different areas.

By using the archaeology focused on death and mortuary practices as an example, this entry outlines the potential of a rich transdisciplinary archaeology, and some of the challenges archaeology faces in fully integrating its different epistemologies. The archaeology dedicated to studying burials and the remains of the dead is an example both of the complexities of archaeological inquiry, drawing on multiple lines of evidence and approaches, and of the potential wealth of information about human lives and deaths in the past. Here, we can study

the remains of the human beings themselves to infer biological and environmental dimensions of identity, including age, sex, health, diet, migration history, and genetic make-up. But mortuary remains are also the material traces of ritual and social practices, which—if documented, visualized, and analyzed with carefully theoretically informed methodologies—can reveal equally significant knowledge about the past, opening up to insights into cultural and social identity, lived experience, social relationships, power, ontology, and the practices that framed the understanding of death among the participants. This work draws more explicitly on the humanities and different kinds of social theory. But as we see strides forward fueled by synergies between scientific methodologies and theoretical approaches, we also see tensions within the field that, if left unquestioned, may grow over the coming years. Archaeological science has made very significant headway in the past decade in ways that immediately engage mortuary archaeology. The rise of “forensic anthropology,” ancient DNA research, stable isotope analysis, and so on has undoubtedly enriched an archaeology that long remained distanced from the potentials of these approaches, relying more heavily on humanities and social theory analysis, missing out on the generation of data that would improve the pathways toward a more multifaceted engagement with traces of the past. With more widespread archaeological use of—and argumentation with—scientific data, it seems that the relevant question is, can the pendulum swing too far? The disciplinary shift has created a situation where new data are generated at a high pace, both because methods have improved and become increasingly accessible to more researchers, and because this archaeology is highly fundable, being so seemingly more concrete in its output of “facts.” Is there a risk that archaeology in this new situation is turning away from problematizing its humanities and social science side, the way some post-processual archaeology in the 1990s turned its back on science? As we witness this surge in data generation, and in scientific competence within archaeology, it is imperative that we also push to integrate

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

DOI: 10.1002/9781119188230.saseas0309

these data with research questions and theoretical frameworks that recognize the complexity of the past in a transdisciplinary way, to protect the complex, rich scholarly value of the discipline.

Pride, prejudice, and power

Contemporary archaeology is still struggling with internal misunderstanding, where the different sides hold reductionist views of one another based on subdisciplinary pride and prejudice. Natural-science-based archaeology often looks at the archaeology anchored in humanities and social theory as too interpretative, as lacking in empirical grounding, and sometimes as too obscure—unnecessarily complicating matters with impenetrable jargon. Similarly, while the humanities-oriented archaeology may yearn for detailed laboratory results, there is a tendency to view the archaeological sciences that produce these as positivist and rigid, not able to theorize, nuance, and problematize in relevant ways. Both these positions are unfair and unproductive. In the case of mortuary archaeology, the scientific analysis of human remains allows assays that can reveal previously inaccessible information about a range of issues including diet, migration, and genetics. These new data undeniably feed into our knowledge about the past and invite us to ask questions relevant to the humanities-driven archaeology. Similarly, these data are enriched by a deep and nuanced understanding of the archaeological contexts and research history, and of how human societies work, something we access through social sciences and humanities. As Lidén and Eriksson (2013) point out, good scientific inquiry is driven by research questions, dependent in turn on transdisciplinary theoretical frameworks. To this we can add that good humanities-driven archaeology is always grounded in archaeological data and evidence. Undoubtedly, the different paradigms rely on each other. I explicitly avoid using terms like “interpretative archaeology” and “theoretical archaeology” here, since they implicitly rely on the false assumption that scientific archaeology is not interpretative or theoretical. A true transdisciplinary archaeology recognizes that all archaeology is methodological, theoretical, and

interpretative, and that it is by integrating the complexities offered by the “other side” into one’s own process of analysis and interpretation that our insights will benefit.

To bridge the rift, we need to recognize the mutual dependency and further develop a literacy across the subdisciplines, allowing us to connect and evaluate the arguments. We also need to foster a more collegial culture in how our results are published and communicated. New detailed information and observations gained from bioarchaeology and novel laboratory methods—from “big data”-driven ancient DNA analysis to mass spectrometry and innovative forms of digital imaging and statistical analysis—have all added to what more traditional archaeological and biological anthropological observations have achieved in the past. Innovative scientific methods allow us to expand our inferences about human societies and populations, about chronology and environment. While the value of these results is undeniable, the ways in which they are presented can actually undermine transdisciplinary dialogue. This is the case when laboratory-driven projects produce reproducible, potentially highly reliable results, yet they are motivated basically by falsifying straw-man hypotheses that only represent a fragment of the scientific work done by previous generations of archaeologists, working with more traditional methods (e.g., lithic or ceramic typology, stratigraphy, settlement structure and patterns). In fitting readily into “It-has-now-been-proven-that” headlines, laboratory-driven research’s big data can come to completely overshadow earlier archaeological support for the hypothesis claimed now to have been so strongly favored. It is good scientific practice in any field to recognize previous research. As archaeologists working across subdisciplinary boundaries, we need to learn how to implement cross-disciplinarity in a way that acknowledges this particular nature of our work. As an example, an ancient DNA analysis looking into the process of neolithization in Europe must not only recognize the relevant research in methodology, population history, and genetics, but also consider in depth independent lines of archaeological evidence for contact, migration, sedentism, domestication, demographic intensification, social inequality, craft specialization, ritual, ontological changes,

and so on. Expecting and encouraging this kind of familiarity would stimulate archaeological research teams to become more diverse, foster a deeper competence in the field, and yield more interesting interpretations, questions, and even methodological innovations.

Similarly, the critics of archaeological science must develop a more generous attitude to the value of the data that are currently produced. At first glance, the results of a study that has sequenced the genome of a single individual (for example, to account for eye and hair pigmentation) may seem trivial to an archaeologist used to working with the larger “big questions” in the field (for example, neolithization) or on broad but critical research questions seeking to problematize identity, gender, and power within communities. But even this collection of presumed trivialities must be viewed through the lens of basic or foundational research, which is, and must be, regarded as valuable in itself. As in other sciences, data revealed from archaeological sources can initially seem trivial, but may eventually become an essential part of a foundation that allows us to gain a better and more nuanced insight into the past. The information about eye and skin color in an individual (e.g., Allentoft et al. 2014) becomes significant the moment we use it to discuss adaptation and gene flow at a demographic level, but also aspects of human life in the past, such as beauty standards, human relationships, identities, and cultural encounters. Similarly, the detailed reconstructions of the handling of the dead body gleaned from the analysis of micro-movements of bones during the process of decomposition in archaeoethnology (Duday 2009) gain their significance as we start to ask questions about why people treated their dead in specific ways (Nilsson Stutz 2003). Even as an isolated observation, such detailed work in mortuary taphonomy feeds our shared scientific understanding of decomposition processes that may become more broadly useful in future research. Natural science approaches thus recognize the value of methodologically reproducible evidence gathering and hypothesis testing, in ways that humanities-oriented research does not, thus supporting value in foundational knowledge building. Critical self-examination and mutual understanding alike are necessary on both sides to reduce the sciences–humanities divide.

Building bridges and looking for the feedback loop

While basic or foundational archaeological science research into skeletal biology, population genetics, or isotope chemistry, and so on is valuable in itself, it becomes *archaeology* when it is framed within a search for insights into human life and death in the recent or distant past. To paraphrase Lidén and Eriksson (2013), it is all about the questions we ask. To accomplish this, a combination of data, scientific analysis, and philosophical and critical social theory is necessary. Methodologically driven empirical approaches in bioarchaeology and forensic science often provide a foundation for scientific studies within a range of fields including burial taphonomy (Duday 2009; Nilsson Stutz 2003), disability (Hubert 2000), illness (Martin and Osterholtz 2016), and mortality and violence (Martin, Harrod, and Pérez 2012). These observations are then subsequently enriched in humanistic inquiry about lived experience and for general theoretical argument about bodily affect, identity, and power, for example. The inquiry ideally works in a feedback loop, allowing all engaged fields to enrich our perspectives on the past. While it is impossible here to give a complete account, I will limit this presentation to a few examples of areas of research where a combination of scientific and humanistic perspectives clearly enriches our insights into the lives and deaths of the people we study and ultimately improves the research quality in all fields.

When looking at a parameter like identity, we soon discover the gains from this type of bridge building. While the term “identity” in archaeology has been problematized and nuanced by the humanities and social sciences (Fowler 2004), it undoubtedly relies on scientific archaeology *as well*. While we can problematize cultural and social age and gender and explore the many ways in which these are affected by, and in turn also affect, culture and social realities, the analysis requires a connection, even when problematized, to biological age and sex. Questions of social class are elucidated and nuanced not only by the material culture associated to the human remains, but also by the macro- and microscopic traces of pathology, nutrition, health status, and so on revealed in scientific analysis. Beyond sex,

age, and social class, we know that health and disability can be fundamental factors in identity production, and these are identified and partially understood through paleopathological analysis. But then, of course, this scientific data must be generated by asking questions that are relevant for the context—insights that can only be achieved through a deep knowledge about the archaeological period and about how human societies work. Even at the level of sampling for isotopes and DNA, the scientist relies on archaeological knowledge about the period (social structure, mortuary practices, contacts, technologies, subsistence, etc.), and more fundamental anthropological and philosophical understanding of how cultures work, to shape their research design. After the analysis, the results must be weighed with this deeper understanding in mind to become archaeology. What, for example, does a nutrition deficiency or a disability mean for an individual within this society? How may these phenomena be noticed and understood within the society? Did people have access to care? Were some pathologies social stigma, or were they actually social assets (e.g., Porr and Alt 2006)? These questions, in turn will be enriched also by the scientific understanding of the effects of food insecurity, disability, and aging. As we proceed to this level we enter a realm of archaeology where we rise above the data and fundamental models, and get to the level of biocultural human lives and deaths. We can elucidate a lived experience of migration that leaves its traces in the isotopic make-up of our bones, of diet, illness, wealth, and poverty. Identity becomes multidimensional and dynamic and can no longer be dissociated from cultural practices and experience, and in turn allows us to connect these multidimensional concepts to others, like food production, health, prestige, power, and economy. Similarly, violence not only is a potential cause of death, but also can be part of a lived experience. When studying violence, archaeology goes beyond identifying it as absent or present, and asks questions about who gets targeted by it, and what this pattern tells us more broadly about the society. How is the violence gendered? How is it related to structures of inequality? Is it linked to conflict between groups? The bioarchaeological approaches to nonlethal violence and how it affects the lived experience of people allow us to ask questions about power and suffering (Martin

et al. 2012). All these questions must be framed within both a broader comparative understanding of violence in human societies and a consideration of the uniqueness of particular cultural contexts. Again, we see how a transdisciplinary archaeology is a case of where the whole understanding is greater than a simple sum of analyses and interpretations. When physical violence or a more silent killer like starvation is the cause of death, the story inscribed on the bones of the dead may be contextualized with all the other information we have about a period in time, allowing us to decipher cases of bodily violence, trauma, suffering, and survival as common or exceptional, ultimately allowing us to get to a better understanding of lives and deaths in this past context.

Death is also a profoundly cultural and social phenomenon, and any study of archaeological mortuary features relies heavily on this understanding. When a person dies, the survivors are left not only with the abstract problem of loss and grief, but also with the concrete biological product of death: a cadaver. The way in which the body is handled after death—which is what we as archaeologists encounter the remains of—is highly variable across cultures and deeply rooted in ontology. To engage with these remains therefore requires a thorough consideration of handling the dead as a social practice that influences but is also influenced by the cadaver. This is the case regardless of specific research question (e.g., about social status, inequality, other aspects of identity, violence). There are fundamental epistemological reasons for this. Without an understanding of the cultural context we are unable to assess the validity of our data, whether it is representative or relevant for the kinds of questions we are asking. But the consideration of dealing with death and the dead also has an ethical dimension that is equally important. As archaeologists, we often work with the remains of people who have not given consent. The least we can do to uphold our professional standards is to explicitly acknowledge that the remains we work with are human remains, often from ritual contexts.

Concluding thoughts

Archaeology is not in crisis. Humanities and social science-driven archaeology is developing

growing practical and intellectual connections with scientific archaeology. This positions our discipline as a dynamic and promising field for robust and thoughtful transdisciplinary collaboration. But as with any academic field, we are facing tensions in moments of growth, and it is imperative that we reduce them before they undermine the dynamic, collaborative work that is being done. To accomplish this, we need to follow a few best practices of transdisciplinary research, including recognizing the dependency we have on one another's insights; becoming literate enough to be able to assess the information provided by other specialized research fields; and explicitly crediting the "other side" for the research they have accomplished, which in turn has stimulated new questions asked.

Humanity and Animality

KRISTIN ARMSTRONG OMA

University of Stavanger, Norway

Humanity is normally understood as that which is associated with human beings, most notably cognitive faculties and psychological characteristics that are generally attributed to human beings and (sometimes wrongly) perceived as unique to humans. These traits are, beyond pertaining to all things human, cognition in the form of rationality, reason, and intellect. Morality and compassion are other traits associated with humanity. This article is mainly concerned with the above description of the understanding of humanity. However, associated understandings of humanity are also important to bear in mind when considering the implications of this definition to archaeology. Associated understandings include:

1. The academic disciplines thought of as the umbrella term humanities (i.e., archaeology, literary studies, languages, history, arts). Universities and other educational institutions are ordered according to this understanding of academic subjects, with separate humanities faculties.
2. Humanitarian work normally associated with charities and non-governmental organizations (NGOs) that work towards bettering living conditions for others.
3. Human nature—the understanding of what it is to be a human and what sets humans apart from other types of beings, more specifically psychological characteristics that are common to members of the humans species, hereunder virtues such as morality and empathy.

Animality is understood as particular traits that are associated with the animal nature. It describes perceived common traits of nonhuman

animals and is used to describe that which is not mindful, nor virtuous, like base instincts, biological drives, and natural, unrestrained, unreasoned responses to physical drives or stimuli. The animal nature is seen as a direct expression of animal behavior, which is interpreted as being devoid of human cognitive abilities such as rational thought and intellectual reasoning, and psychological characteristics such as empathy and morals. For example, more specifically, lack of capacity for language is associated with lack of cognitive functions such as memory, intention, planning, and ultimately agency. Thus, animality encompasses the “brute beast,” governed by pure instincts.

Therefore, it is to a large extent defined in relationship to, as well as seen in opposition to, humanity and denotes what humanity is not. Traditionally in western science, animals of various species are understood as beings that lack the faculties of humans, such as intentionality, cognition, language, creative art, and the ability to create and sustain complex societies. As will be described below, new and ongoing scientific experiments—particularly in biochemistry and neuroscience—are increasingly challenging this understanding of animal nature and thus the concept of animality.

Archaeology is founded on the basic premise that humanity and humans, are an entity apart from—although not physically separated from—the rest of the natural world. Humanity is understood as expressed and materialized as human cultures. These past cultures make up the main study area of archaeology. From the point of view of archaeology, humanity consists of traces of humans and their activities, hereunder hominids, and the traces of the societies that humans have lived in. A presupposition that humans are a species set apart from all other (animal) species underlies this way of thinking. Inasmuch as natural sciences play a part in archaeological interpretation (e.g., paleobotany and osteology) they are relevant when they can inform on how past human cultures left imprints on the natural world, such as the cultivation of grains and the domestication of animals. A

human killing a bear is therefore of interest to archaeology, and a bear killing a human—but not a bear killing a bear.

Main strains in western philosophy have solidified this way of thinking, particularly in the Enlightenment movement, which modern academic traditions rest on. Famously, the philosopher René Descartes (1596–1650) with his ideas of humans as beings with minds and souls, as opposed to animals as automata, phrased enlightenment in his cogito sentence: “I think, therefore I am.” His ideas have been very influential regarding how humans in the western world have come to understand themselves as just that (e.g., Brentari 2016).

Descartes and other philosophers have been instrumental in creating an ontological system with a hierarchy of beings with humans on top, and these notions are mostly implicit and unexpressed. Philosopher Carlo Brentari suggests that

The superiority of man ... is seen as depending on the presence of an element, structure, or instance that is ontologically different from all other entities in the world, which grounds and justifies any other form of superiority. (2016: 127)

There is, according to this understanding, a difference of kind between human and nonhuman animals. Archaeology and its place in the humanities is also prejudiced by the tacit assumption of man’s superiority.

Lately, academics have begun to question human superiority. Anthropologist Anna Tsing (2012) describes traditional science as human exceptionalism, and as a “normative fantasy” in our culture. She claims that

Science has inherited stories about human mastery from the great monotheistic religions. These stories fuel assumptions about human autonomy, and they direct questions to the human control of nature, on the one hand, or human impact on nature, on the other, rather than to species interdependence. (2012: 144)

But, she posits, “What if we imagined a human nature that shifted historically together with varied webs of interspecies dependence?”

Sometimes animality has been referred to as traits in humans that are seen as undesirable, like lack of restraint in various ways, hereunder sexual instincts, gluttony, unacceptable violence (Brentari 2016: 128)—the alleged “animal nature” of man. This reveals some of the problems with these terms—humanity is an ideal rather than an actual description of what it is to be human. Humans are also, biologically, animals, and as members of the animal kingdom humans therefore share many traits and characteristics with other animal species, from anatomical traits such as a spinal column and a digestion system, and manner of reproduction, to communication systems by sound and bodily gestures. Lately, research on animal and bird cognition has taken giant steps forwards, as researchers are increasingly improving designs to study animal cognition not as a lesser copy of human cognition but as unique to each species. These studies include parrots that can distinguish colors, shapes, can spell and do maths, corvids that use tools, can evaluate speed limits on roads and whose intelligence seems to be converged with primates, and primates that can do advanced maths and recognize and remember numbers at a speed that no human can hope to achieve. Also, insects such as termites, bees, and ants form complex societies with advanced communication systems, and beavers create built structures. Not just cognitive structures have come under scrutiny, studies also show that animals may feel empathy and act accordingly, as well as having a moral compass (e.g., De Waal 2009). These examples demonstrate that animals share more traits with humans than previously recognized.

What is it, then, that separates humans from the rest of animal kind? Some argue that the separation between humans and animals is of degree rather than kind, i.e., that different animal (hereunder human) species share basic core traits, and they differ in the level of ability and capability, rather than a black and white have or have not. Thus, humanity and animality are, in terms of physicality, not mutually exclusive. In fact, common usage of animality includes humans (although undesirable and so-called base human instincts, actions, thoughts). Rather, according to the common usage of the terms, humanity and animality are sliding scales.

Humanity is, according to this definition, the gold standard of rationality, however, archaeology (and anthropology) teaches us that each culture has their separate understandings of the world and “how it works,” in other words, different ontological rationales. When considering past societies it is therefore important to bear in mind that ideas of what is rational is not a cross-cultural given, rather, understandings of the ontological ordering of the world will normally differ between societies. Likewise, ideas of what constitute the natures of different beings are subject to different understandings. The definitions that archaeology, as well as normative sciences, operates with, regarding humanity and animality are, thus, a historically specific product of the way western science understands the ontological nature of being. This is important to bear in mind when studying past societies, in which radically different understandings of the nature of being would have been formative for every aspect of life, such as the social, economic, and religious parts of existence.

Further, the lives of humans and animals should be studied in particular historical settings so as to allow for an investigation into the unfolding of culturally and historically situated ontological status of beings. This entails that just as different categories of humans are studied—based on gender, age, social status, and so on—rather than regarding humans as one undifferentiated category, animals should also be considered according to species, age, and gender.

The archaeological discourse on animals has traditionally been devoid of the potential agency of animals, but rather focused on animals as either container for human symbolism, as economic strategies, or as conglomerations of passive materials for humans to shape (Armstrong Oma and Birke 2013). As in the humanities at large, human agency has been granted supremacy. This attitude has seeped into archaeology by way of the Enlightenment roots of the humanities. In a philosophical sense this entails that ontologically the nature of being is the nature of human being; the nature of action is of human action (Johannsen 2012: 305). But animals are more than cultural abstractions: what is lacking is considerations of the animals *as themselves*. However, currently there is a growing recognition that many animals possess characteristics

such as intelligence, emotion, and awareness that vary from humans by degree rather than kind (Shapiro and DeMello 2010). Animals are alive, active participants in their worlds, and the spaces where those worlds intersect and enmesh with humans are often messy and difficult to divide into clean compartments. In addition to how humans “use” them, animals often take part in subjectified relationships with humans that impact both species at various levels of scale. For example, Birke, Bryld and Lykke (2004: 172–3) describe how rats in labs defy their definition as “data” for animal experiments by requiring that humans facilitate their biological and social needs and perform accordingly.

The debate as to which factors should be present to qualify as agency ranges from intentionality, free will, and morality. New research in biology and ethology is constantly challenging the common perception of such qualities as human-only and bridges the gap between humans and animals. McFarland and Hediger (2009: 8) puts it thus: “no matter how we consider agency, the result is that either humans are more like the other animals or the other animals are more like humans than we have comfortably thought in the past.”

Bearing this in mind, it may in a number of ways be relevant to archaeology to also include animals as social agents in research on past societies. One poignant example is domestication, which led not just to domesticated animals becoming a “walking larder” but also led to new ways of living together with different species. Domestication led to changes beyond the genetic engineering of the domestic animals that came to depend upon humans. For example, a specific material culture, architectural structures, and interactions with the landscape that led to environmental changes. A useful approach in understanding how animals played a part in such processes is found in the growing interdisciplinary field human–animal studies.

Human–animal studies (HAS) is a newly established interdisciplinary research field that has seen an immense growth in the last few years (Shapiro and DeMello 2010). Several journals are devoted to the field, such as *Society and Animals*, *Anthrozoos* and *Humanimalia*, and Brill publishes a series called HAS (short for

human–animal studies). Large international conferences are held, for example under the umbrella of the loosely knitted organization Minding Animals.

The objective of HAS is to examine the complex and multidimensional relationships between humans and other animals, and it “embodies a sustained interest in understanding and analysing how we humans relate to and make sense of other species” (Birke and Hockenhull 2012: 3). HAS comprises work in areas of study such as psychology, sociology, anthropology, political science, history, literary criticism, and other disciplines in the humanities (see <http://www.animalsandsociety.org/pages/human-animal-studies>). A plethora of research questions emerge from this platform, examples range from animal-assisted therapy, wildlife conservation, to questions of animal advocacy, and rights. An outspoken position of animal advocacy is frequently found. Shapiro and DeMello (2010) point out that the combination of advocacy with scholarship is currently perceived as less threatening, as the thrust of contemporary philosophy of science challenges the traditional view that it is possible for a scholar not to have a position on the material under investigation. The thing is, as Birke and Hockenhull (2012: 4) point out, understanding multiple forms of human–animal relationships “requires thinking laterally, to interrogate widely diverse ways of observing and theorizing, and to be able to draw on diverse disciplinary approaches.” This broad platform includes, for many, a personal investment with the issue at stake.

For a large part, the archaeological literature on animals is, as previously stated, within the bounds of animal studies, and perceives animals as human constructs. However, there are exceptions, namely archaeologists that work within HAS (see for example *Society and Animals* 21 (2) from 2013, which is a special issue on archaeology). HAS allows the animals to be objects of study, but they are also sanctioned as subjects. Academic works within this field own up to the fact that for animals to be studied as social constructions—and to understand the meanings of those constructions—the question of who and what the animal in itself is must be addressed first, such as their social and cognitive abilities and behavior (Shapiro and DeMello

2010). Meaning emerges through experience, for human and nonhuman animals both; also in the way humans understand and interpret the inner world of animals.

Recent research on biochemistry has demonstrated that it is indeed possible for humans to grasp the emotions and feelings of other species, by way of the biochemical phenomena of the hormone oxytocin (Olmert 2009) and brain cells termed mirror neurons (Iacoboni 2008).

Archaeology holds the potential to be a very important discipline for the development of HAS since archaeology can add a unique diachronic perspective, exploring the coevolution of species, and adding time depth to issues that concern human–animal studies (Armstrong Oma and Birke 2013). In the deepest sense, archaeology can, by way of studying human origins, ask fundamental questions about what it is to be a human animal, and thus decenter the human species, pushing us off our self-appointed throne of species supremacy (see Gittins 2013).

Inhabited Landscapes

IAN J. MCNIVEN

Monash University, Australia

One of the many delights of undertaking indigenous archaeology and working closely and collaboratively with indigenous communities is that you often hear statements that jolt you out of the complacency and normativeness of western thinking. In early 2016, during the course of a conversation with a senior elder of central Torres Strait over why government authorities need to engage Torres Strait Islanders more meaningfully in local environmental management, I was told simply that “We are the environment.” I knew immediately that this statement was not a reference to a western romanticized notion of Torres Strait Islanders being a part of nature or living in harmony with nature. This statement had a more profound ontological message that sidestepped western dualist thinking about a division between culture and nature, and between people and the environment. It signaled that the environment does not sit outside of humanity awaiting engagement (and management) but exists only in its relationship *with* people. This human-centered view of the environment goes to the heart of conceptualizing and understanding inhabited landscapes.

The theoretical work of the anthropologist Tim Ingold heavily informs archaeological conceptualizations of inhabited landscapes. Critical is Ingold’s (1993) phenomenological dwelling perspective which draws on notions of dwelling and being-in-the-world, expounded by the philosopher Martin Heidegger. In this conception, landscapes are an enduring record of human dwelling and the lives and associated labors of past generations. As dwelling by definition is an ongoing process, human–environment interactions are similarly ongoing. Thus, inhabited landscapes are always under construction and works-in-progress, with intrinsic and inherent temporality.

A dwelling approach to inhabited landscapes challenges the culture/nature duality of western thought. Externalization and objectification of the environment are expressions of a Cartesian dualist ontology developed as part of European Enlightenment thinking in the eighteenth and nineteenth centuries. In this connection, anthropologist Philippe Descola (2013) explores the development and expression of the nature/culture dualism in western thinking and how this contrasts to the animistic and totemic ontologies of other societies, especially indigenous peoples of the New Worlds of the Americas and Australia. Descola points out that in a western dualist (naturalistic) ontology, nature (and by extension the environment) is positioned as an external and autonomous entity to humanity such that it becomes available for objective study. As such, archaeologists come to rely on scientific and universalistic characterizations of an external nature (environment) to which diverse peoples and cultures adapt.

Although archaeologists have worked closely with paleoenvironmentalists over many decades to develop robust scientific techniques to characterize the environments of peoples of the past, such characterizations are only one dimension of landscape archaeology. Researchers need to be aware that an approach that ontologically, epistemologically, and analytically separates environment as an externalized and objective entity to culture produces information that is relevant to a culture/nature dichotomy. In this conception, the environment has an objective reality beyond people who subjectively perceive and engage with only a subset of the environment as they enculturate spaces as places. In contrast, an archaeology of premodern-inhabited landscapes sees nature (and the environment) as an internalized and subjective entity that is understood through bodily immersion and experience. Environmental perception and engagement are not part of the language of inhabited landscapes (Thomas 2012).

Each generation inherits not only cultural sites and places of meaning, memory, and history,

but also environments and ecological processes which have been molded, manipulated, and transformed by their ancestors. This dynamic relationship has parallels with what the evolutionary ecologist John Odling-Smee (1994) refers to as niche construction, whereby the cultural inheritance of societies also includes ecological inheritance and the continuity, either intentionally or unintentionally, of humanly modified ecological processes. The result is that the relationship between people and their environment is not only dynamic but also mutually constitutive. Thus, inhabited landscapes take shape as the cumulative product of the mutually constitutive and mutually transformative interplay of people–environment relationships and interactions. Ingold (1986, 2) reminds us that “an environment can only be defined relative to a being or beings whose environment it is.”

No landscape or environment comes ready-made for human habitation. Something has to change: either cultural behavior and/or the environment itself. Because such changes are invariably cumulative, the process of change is never a one-off event because the desired state of inhabitation is always unfolding and always a work-in-progress. Thus, the quest for archaeologists is to characterize past environments not as external backdrops to cultural practices but as internal expressions of the rhythms of life and the cumulative products of cultural practices and long-term human interactions. To assume that particular peoples of the past had no impact on their environment not only implies that their environment was presuited for inhabitation, but also posits a passive ecological state virtually unknown for higher-order organisms. This process is analogous to the process of owning shoes. We purchase shoes with an understanding that it is only through the process of wearing the shoes that they become worn-in as they accumulate subtle morphological modifications to increasingly mold to the unique form of our feet and our lifestyle. As such, our shoes are always a work-in-progress, accumulating historical and symbolic dimensions through the historical process of wearing. Inhabited landscapes are worn-in landscapes.

A critical point to remember with inhabited landscapes and a dwelling perspective is that

new environments are not engaged in externally and perceived through the subjective lens of culture. Even if people enter places never visited or seen before, they have an immediate prediscursive preunderstanding that makes interaction possible. The plants, animals, topography, and even weather may be unfamiliar but never so unfamiliar that it is impossible to traverse through that landscape. Indeed, new environments neither exist outside of our own embodied interactions with such places nor have an objective reality beyond that interaction. It is for this reason that no environment is truly alien, even in situations of colonization where people enter new worlds. Colonizers do not enter new worlds and begin to modify such places such that dwelling can take place. Places are modified because the decision to stay has already been made. In an analogous sense, every archaeological site survey is a form of embodied dwelling such that it is possible to identify new artifacts such as flaked stone tools of which no two are identical.

A key environmental approach to operationalizing inhabited landscapes is engineered or constructed landscapes and the three processes of inclusions, exclusions, and transitions. Inclusions involve the deliberate movement of selected plant and animal species by people from one environment to another. While the best documented and understood archaeological example of this process is the movement of domesticated plants and animals, Pleistocene hunter-gatherers also employed this process. Exclusions are the deliberate quarantining of areas from the introduction of certain plant and animal species usually to avoid negative environmental impacts. For example, the spotty distribution of domesticated pigs across the Pacific may relate to different island communities responding to the known capacity of pigs to destroy horticultural gardens. Introduction of pigs comes with a requirement to build fences around gardens, whereas exclusion of pigs avoids the need to build garden fences. Transitions are the most common form of environmental engineering documented by paleoenvironmentalists. This process involves in-situ manipulation of endemic ecological processes to bring about some form of desired environmental change, usually enhancement of particular resources. Perhaps the best documented example of this process is landscape burning to increase the availability of

selected plant and animal species. With all three processes, intended changes may also have short- or long-term unintended consequences. In some cases, the long-term cumulative impact of unintended consequences may present new resource opportunities. For example, slope erosion through landscape burning may lead to coastal progradation and new opportunities for habitation and cultivation of crops. Similarly, long-term occupation of campsites by hunter-gatherers can result in unintentional establishment of garden groves through cumulative germination of discarded plant foods and cumulative soil fertility from organically rich occupation deposits. In this sense, inhabited landscapes are worn-in landscapes and worn-in environments.

Environmental change linked to long-term dwelling creates a situation where all inhabited and constructed landscapes are to varying degrees also domesticated landscapes (Terrell and Hart 2008). In this formulation, the concept of domesticated landscapes has particular analytical potency for hunter-gatherers where long-term use of particular plant and animal species alters local ecologies. That is, these ecologies only maintain their altered state as a result of constant human use and intervention. As such, and in keeping with the concept of inhabited landscapes, all domesticated landscapes are constantly under construction and always unfolding as works-in-progress. While, in some circumstances, intensive intervention in local ecologies may result in formal domestication of plants and animals (e.g., morphological and genetic changes), such formal change is not a necessary condition of domesticated landscapes. In other circumstances, alteration of local plant and animal ecologies may be indirect through alteration of related environmental features. A good example of this indirect alteration is manipulation of local hydrologies through modification (e.g., damming) of local waterways to enhance the habitat, availability, reliability, and capture of key aquatic resources (e.g., birds and fish). Clam gardens on the Northwest Coast of North America indicate that such manipulations also extend to marine environments and seascapes.

Intended and unintended consequences reinforce the view that constructed landscapes are

always in a state of emergence and are never finished. Furthermore, constructed landscapes are recursive such that people shape environments but environments also shape people. From a dwelling and mutually constitutive perspective, people can be seen as orchestrating the deterministic qualities of environments of their own construction. In this connection, the anthropologist Roy Ellen (1982) makes the important point that many correlations between culture and environment are in fact correlations between human behavior and the ecological products of that behavior in the form of a modified environment.

The notion of constructed landscapes as the temporalized cumulative product of past human actions and ongoing human interactions reveals that inhabited landscapes are also inherited landscapes. That is, each generation inherits not only the products of their ancestors' labors but also the practices to allow potential continuity of processes of environmental interaction and manipulation. While each generation exercises agency and can choose whether or not they wish to continue such processes into the future, they have no choice in the inherence of the products of the past application of such processes. It is in this context that all inhabited landscapes are also historically contingent landscapes (Barton et al. 2004). Yet such landscape inheritance is rarely complete beyond the products of the past labors of the previous generation in terms of modified environments and material objects. As the generations pass, the potential for past landscapes to endure decreases as generations decide to invest less and less in the maintenance of processes that ensure continuity of the form and knowledge of the fruits of past labors. In extreme cases, the fruits of past labors become pruned and transformed beyond recognition and even forgotten about and lost. Archaeological research is founded upon a desire to selectively rediscover and reimagine the material expressions of these forgotten and lost labors.

Perhaps the most challenging aspect of a dwelling perspective to inhabited landscapes is the place of nonhuman persons and spiritual entities. Anthropological research reveals that indigenous people inhabit animate, sentient, and intentionalized land- and seascapes where the social and agentive domain of humanity is not limited to human beings but also

includes many plants, animals, objects, and spirits (Descola 2013). As such, humans interact with this broader humanity not through ecological relationships and the objective currencies of resource maximization and calories but through social relationships and the subjective currencies of reciprocity and morality. As such, an important dimension of the inhabited land- and seascapes of peoples of the ancient past is spiritscapes and spiritual forces that were engaged ritually, often at formally constructed sites (e.g., shrines), as a normal part of dwelling.

Of immediate concern is the role of spiritual forces in human–environment interactions and the extent to which spiritual forces could be manipulated by people to alter the nature of such interactions. For the most part, people engaged spiritual entities and associated forces through specialized ritual performances. These interactions usually were associated with increasing the ability of hunters to obtain prey (both terrestrial and marine) through what are often referred to as hunting magic rituals, and with increasing the availability and fertility of selected plant and animal resources or altering key elements such as wind and rain through what are often referred to as increase rituals. In some respects, hunting magic and increase rituals can be seen as a dimension of engineered or constructed landscapes. However, a dwelling perspective redirects attention away from such a utilitarian perspective to one where such rituals form part of the ongoing lived expression and experience of the ontological status and relationality of humans and nonhuman persons.

The spiritual dimensions of dwelling and inhabited landscapes also involve the agency of ancestral beings, including the ancestral dead. Often this ancestral agency, power, and potency is strategically engaged, released, and expressed through hunting and increase rituals. While such interactions have an immediate impact on people, they also can have more profound implications in terms of ensuring continuity of the world. This process is illustrated well by the Dreaming ontology of Aboriginal Australians and their associated landscape concept of country. For Aboriginal Australians, ancestral Dreaming beings created not only the world but also humanity. Dreaming beings invariably are linked to, and often embodied as, different

features in the landscape of their creation and transformation. Land ownership among Aboriginal groups is usually linked to these Dreaming beings and emplaced features. With the rights to land ownership and associated resource use come ritual responsibilities to ensure continuity of Dreaming being forces and associated resources. Although ancestral creator beings existed before people, it is only through human dwelling in the totemic landscape that these ancestral beings and forces are renewed and become efficacious and generative in the present. Indeed, it is only through the temporal process of dwelling that Aboriginal people increase in age and seniority to take on the corresponding increasing complexities of Dreaming knowledge and law that are expressed through rights, rituals, and responsibilities. Critically, Aboriginal people learn about their ancestral past by moving through the landscape in the company of elders (Morphy 1995). The ancestral past (as the basis for Aboriginal sociality, identity, and belonging in the present) is revealed as a dimension of place not time. In this conception, the inhabited landscape as an ancestral landscape is expressed and given form through human experience.

Interpretation

PHILIP TONNER

University of Strathclyde, UK

An interpretation is a theoretical or narrative account of “something,” whether it be facts, events, persons, or texts, that makes that “something” comprehensible. In archaeology, the “something” in question is the archaeological record: archaeology, being the discipline that studies the human past through its material remains, offers interpretations of that past. Interpretation makes sense of archaeological evidence (Tilley 1993). Archaeologists must engage in an “interpretive leap” when moving from excavated data to final report (Trigger 1996). They do this by way of what Gamble (2008) has called the “archaeological imagination.”

In the human sciences, more generally, it is possible to distinguish “historical interpretations” from “scientific explanations.” Historical interpretations are based on human experience, understanding, and language, whereas scientific explanations are based on observations that are abstract, constructed, and theoretical. In archaeology the concept of interpretation has gone through a number of different theoretical phases. Each phase has bordered on historical interpretation or scientific explanation to varying degrees. A broadly culture history approach remains a mainstay of archaeological interpretation. Thomas (1995) argued that much of the work produced by academic archaeologists in the United Kingdom, for example, still broadly conforms to this approach. Culture history approaches in archaeology prioritize the gathering of data, the establishment of facts, and the creation of appropriate classifications of that data. An emphasis on inductive reasoning, bringing this approach into the borderlands of scientific explanation, where the interpreter moves from their specific observations to making more general claims that are supported by their observations is a central plank of culture history

approaches. It is chronological and geographical ordering of data that is paramount for culture history approaches and it is new data, rather than new interpretive frameworks for that data, that is believed to drive the development of archaeological understanding. As witness to this, Gamble (2008) notes that Gordon Childe’s *The Dawn of European Civilisation* went through six editions between 1925 and 1957. Interpretation, historical or otherwise, beyond what can be discerned by the attentive archaeologist looking out for indications of change (in both chronological and geographical directions) in the data of the archaeological record, is typically regarded as speculation (Gamble 2008, 23).

In the 1940s and 1950s, owing to a generalized cultural positivism (see POSITIVISM) and/or empiricism (see EMPIRICISM), interpretations of the archaeological record were taken to be subjective—matters of opinion without lasting importance (Trigger 1996). For archaeologists such as Glyn Daniel, Stuart Piggott, and Christopher Hawkes it was archaeological data that was taken to be central to the discipline. Whereas data are objective, interpretations, by contrast, are shaped by intellectual fads and can be undermined by new and improved understanding of data. Figures like Daniel, Piggott, and Hawkes were, in part, reacting to the influential work of idealist philosopher and archaeologist Robin George Collingwood (1889–1943) who had denied that facts and theories were distinct from one another. Collingwood argued that archaeological interpretation is an activity whereby a modern archaeologist attempts to relive the past in their own mind by way of their ideas: these ideas are about the ideas that past peoples had in their minds. It is these past ideas that shaped the archaeological record. By reconstructing these past mental activities that shaped events, modern archaeologists could hope to articulate the archaeologically visible dynamics of ancient cultures (Trigger 1996, 303–305).

Writing in the 1970s during the heyday of “new” or “processual archaeology,” David Clarke argued that archaeologists utilize five bodies of

theory in their intellectual leaps from data to final report, the final body of which he termed “interpretive theory.” Clarke was skeptical of the broadly intuitive approach used by culture historians in the construction of their historical narratives. He believed that these narratives proceeded without a duly rigorous analysis of the archaeological data which would extract as much information on past behavior as possible. Clarke went so far as to suggest that such narratives represented an “irresponsible art form” (Trigger 1996, 430).

The first body of theory noted by Clarke is “predepositional and depositional theory.” This covers relations between human activity, social patterns, and environmental factors, and with the samples and traces found in the archaeological record. The second body of theory, dubbed “postdepositional,” examines natural and human processes affecting the archaeological record. This includes factors from natural erosion to traces of plowing. Third, “retrieval theory” deals with relations between what survives in the archaeological record and what is recovered in research. Fourth, “analytical theory” deals with how the data recovered from the archaeological record are treated. As such, analytical theory includes varieties of classification and modeling, testing, and experimental studies. Finally, the fifth body of “interpretive theory” concerns the relations between the archaeological patterns discerned at level four (analytical theory) and the unobservable ancient environmental and behavioral patterns that they express. As Trigger put it, Clarke’s interpretive theory “infers the processes that predepositional theory explains” (Trigger 1996, 432). In Clarke’s view, the challenge facing archaeologists is to establish appropriate bodies of theory for each level of analysis. This will involve incorporating analyses from the biological and physical sciences as well as from archaeology, since the human sciences are taken to be restricted to the predepositional and interpretive levels of analysis. Clarke believed that taken together in its entirety, this “theory,” in combination with more broadly philosophical issues relating to logic, metaphysics, and epistemology, would combine to create a truly scientific archaeological discipline (see SCIENTIFIC PRACTICE).

Processual archaeology conceived of archaeology as anthropological science. It is not

specifically allied with humanistic disciplines, such as history. Processual archaeologists value explanation, via methodologies modeled on the hard sciences, over description and/or historical interpretation. Archaeological explanations will incorporate particular observations of the material past drawn from the archaeological record and will incorporate these into cross-cultural generalizations that relate to both natural and social processes. This emphasis on processes is where the designation “processual archaeology” originates. Earlier emphasis on “laws of human behavior” in archaeology is replaced by a concern with the formative processes of the archaeological record itself. Identification of regularities in the record will allow for inferences about processes “to be made from material remains” (Shanks and Hodder 1995, 3). Processual archaeology, which took for itself the title of “new archaeology,” aimed to discover knowledge of the past that, in aspiration, was objective, neutral, timeless, and singular. Despite these aspirations, the fate of interpretation in archaeology did not stop there. Starting in the 1970s, an alternative to this approach began to develop. This alternative tendency was named “post-processual archaeology” by Ian Hodder in 1985. In 1991 it was dubbed “interpretive archaeology,” again by Hodder (Hodder 1991; Trigger 1996). The epithet “interpretive archaeology” is intended to be a positive label for a number of diverse approaches grouped under this banner, in place of the lesser relational title “post-processual” (Shanks and Hodder 1995). Hodder described interpretive archaeology as being characterized by a “hermeneutic method,” and by 1995 he and Michael Shanks suggested that the term “interpretation” itself is the term that will help to clarify current debates in archaeological theory between processual and post-processual archaeology in the English language.

Shanks and Hodder describe interpretive archaeologies as follows: archaeology is a material practice in the present that makes “things,” interpretations, narratives, reports, and so on out of the archaeological record. These “artifacts” are no less truthful for being produced by researchers. In the foreground of the archaeological enterprise is the interpreter, the archaeologist. Interpretation is a form of practice that requires the interpreter to take responsibility for their interpretations. Like other social practices, archaeology is concerned

with “meanings.” That is, the job of archaeology is to make sense of things and, because of this, archaeology will be inherently interpretive. Importantly, because it is an interpretive practice, the project of archaeology will be ongoing: no final authoritative or definitive account of the past is possible. As a process concerned with meaning or understanding, the concern with causal explanation is diminished in interpretive approaches. Different interpretations of the same subject matter are possible: multivocality (see *PLURALITY AND MULTIVOCALITY*) is embraced and so a plurality of different archaeological interpretations can be produced. These interpretations will reflect different needs and desires. Interpretation is creative (see *CREATIVITY*), but it is not uncritical. The needs and desires of interpreters and of groups and communities who have an interest in the material past must be recognized (Shanks and Hodder 1995, 5; Jones and Alberti 2013).

The question “What is interpretation?” is still an open one in archaeology (Jones and Alberti 2013). Over the last decade or so, theoretically oriented archaeologists have moved away from asking broadly epistemological questions, such as “What constitutes archaeological knowledge?” and toward asking ontological ones, such as “What is the nature of archaeological thought?” What Lucas (2012) has called the “current interpretive dilemma” is bound up with questioning the underlying ontological commitments and metaphysical assumptions of archaeological discourse. Rather than seeking to remove interpretation as the primary goal of archaeology, contemporary theoretical archaeologists seek to question the nature of the interpretive process and of the archaeologist’s role in it. This emphasis on questioning follows the identification of a worry that one of the consequences of the emergence of interpretive archaeology, which foregrounded the role of the interpreting archaeologist in the present, was to construct a vision of past human agents as essentially “interpreting subjects.” While archaeologists might always aim at providing an interpretation of the archaeological record, archaeological questioning has now recognized that interpretation and reality are coemergent. That is, all practices, including archaeology, are taken to be “fully relational and constitutive” (Jones and Alberti 2013, 15). This

change in perspective in contemporary theory moves away from placing the interpreting subject, as an individual identity, at the center of things. This move is also skeptical of the view that the human subject is the only being capable of action and interpretation. Human subjects too are taken to be fully relational and performative constructions. The interpreting subject is rethought as relational and as something that emerges within a set of unfolding relationships. The shift from epistemology to ontology in archaeology does not herald the “death of interpretation” or the “death of the interpreting subject,” but it does place emphasis on the very constitution of “humanity,” taken as a specific subjectivity, in both the past and the present, as well as questioning the constitution of archaeological interpretation. Rather than representing a radical break with earlier interpretive archaeologies, recent theorists have instead revisited a shared group of influences, such as Martin Heidegger, Michel Foucault, Gilles Deleuze, and Felix Guattari, with fresh eyes and questions, and so possibilities for interpretation.

Knowledge and Inference

MICHAEL FOTIADIS

University of Ioannina, Greece

Archaeological knowledge consists of descriptive statements and explanatory hypotheses, and both of these are intertwined with images. Descriptions pertain to observations made during field and laboratory research. Explanatory hypotheses, on the other hand, are solely the product of inferences. The latter play a most fundamental role in the formation of archaeological knowledge. The everyday work of archaeologists entails that they infer from the residues of past actions the nature of those actions. Observing what is at hand in the present, they work back to the unobservable circumstances that could have brought it about. This process has repeatedly been considered to be analogous to the “method of Zadig” (briefly, the identification of an animal’s species and condition from the tracks it leaves on the ground). In fact, it is considerably more complex. That complexity is due to the palimpsest-like nature of the archaeological record (see *ARCHAEOLOGICAL RECORD*).

Not all of the archaeologist’s knowledge consists of inferences concerning past actions, however. A substantial portion of it consists of descriptions, in technical language, of observations made in the course of field and laboratory research. Such descriptions may at a later stage of the research be used in inferences about past actions. Even when they are not, however, they are still important in knowledge formation: They force the archaeologist to pay attention to details without judging in advance their significance. For that reason, the requirement for adequate descriptions is a standard part of the protocols to be followed in field and laboratory research. When researchers do not adhere to it, their conclusions are likely to be regarded with skepticism, and even ignored by the scholarly community. Because of the importance accorded to descriptions, learning to describe the observable in

appropriate technical terms is an essential part of a novice’s training.

As a rule, descriptions (to a lesser extent, explanatory hypotheses too) are accompanied by images: photographs in various scales, from microphotographs to satellite imagery, drawings, and graphs. Such images carry considerable cognitive weight. They are of equal value to the descriptions and are to be consulted along with them. Their great virtue is that they contain knowledge that cannot be effectively rendered in propositional language, for example, textures, spatial relationships, and synopses of quantifiable data. Archaeology’s knowledge claims have long been substantiated by reference to such imagery. Beside their documentary role in the archaeologist’s research report, images have many other uses. They also serve, for instance, as aides-memoires for the professional and as working objects (*Arbeitsobjekte*) in modeling alternative explanatory hypotheses. They serve as devices for training the novice’s eye. Placed side by side on the printed page, they enable comparisons among artifacts from different geographical locations and periods, and they make possible the communication of one’s discoveries to the world at large. In short, imagery is present in every stage of the archaeologist’s formation and professional life. It is essential for his/her training, in field-work, in the documentation of research results, and in their transmission to professionals and the lay public. Archaeological knowledge turns out to be to a most substantial degree visual.

Naturalistic, highly accurate images of archaeology’s artifacts, the work of professional illustrators working together with archaeologists, were already in circulation in the eighteenth century. The crucial role of visual knowledge in archaeology was not, however, explicitly acknowledged until the turn of the twentieth century (Petrie 1904). Discussions at that time concentrated on the merits of photographs (reproduced in archaeological journals by half-tone technology since ca. 1900) in comparison with the virtues and limitations of drawings. Still, published illustrations of archaeological objects in the

first half of the twentieth century were as a rule of a diminutive scale and too sketchy to afford sharp views of the objects depicted. Visual knowledge at the time was transmitted less through published articles than by means of private communication: Archaeologists exchanged quality photographs with one another and also visited one another's excavations and inspected the finds. Their published knowledge claims were based on such first-hand experiences. This began to change in the 1960s, following, on the one hand, the institutional growth of archaeology worldwide and the ensuing rise in numbers of archaeologists and field projects and, on the other hand, the progress of the information age. Theoretical treatises in the 1960s insisted, for example, that ancient artifacts are "congealed information" of a great variety (Clarke 1968, 120) and that archaeological illustrations ought to be "selective"—that is, present the viewer with useful information free of irrelevant detail. Visual knowledge came of age in the course of the next 50 years. The process culminated in the first decade of the twenty-first century, as journals of international circulation began publishing their full content in electronic form. This allowed for the publication of color images of all kinds, including complex, multilayered graphs. Today, high-resolution color illustrations have in large part replaced black-and-white ones, and the trend will, no doubt, be carried further. The advent of color may have had little direct effect on the epistemic substance of archaeology's knowledge claims. It does, however, facilitate perception and, hence, the transmission of knowledge to colleagues, students, and the public. High-resolution color illustrations are, therefore, justifiably regarded today as an improvement over earlier modes of archaeological illustration.

Archaeological knowledge is multifarious par excellence. In the nineteenth century, even before the great antiquity of the human presence on our planet was confirmed by expert observations (in 1859), geology and paleontology were drawn upon in arguments favoring one or another view regarding that issue. Boucher de Perthes in the 1840s, for example, advocated the view of a deep human past on grounds that he had found primitive stone tools in geological strata that also contained fossil bones of extinct mammals. Provenience studies of prehistoric pots, based

on petrographic examination of clay composition, were attempted by the 1860s. Geology, paleontology, and petrography continue to be important sources of archaeological knowledge in the present, but the spectrum of such sources has in the meantime, especially since the 1950s, greatly expanded. Research reports today are routinely coauthored by scores of experts, the majority of whom are devoted to fields only indirectly related to archaeology. Such fields range from palynology to paleogenomics and from the study of sediment micromorphology to stable isotope analysis of marine shell and human skeletal remains, not to mention studies of diet, based on the examination of food residues on ceramic cooking vessels or in Neanderthal dental calculus. In brief, archaeological knowledge in the present is the product of a synergy of agencies, associations that include experts in a variety of specialized fields, laboratories, and their equipment and institutional support, as well as the material agencies of the objects under study (see MATERIAL AGENCY).

While protocols specify procedures in the field and the laboratory, the development of explanatory hypotheses, relating the observable residues to unobservable sequences of past actions, is a creative process constrained by few rules. Furthermore, no enduring "gold standard" exists with regard to what constitutes an adequate explanatory hypothesis. In the heyday of processual archaeology (the 1960s and 1970s) it was first thought that explanations ought to appeal to general "covering laws" (e.g., laws of culture change), just as the natural sciences appealed to laws of nature. A subsequent, more pragmatic version of this stated that the plausibility of a hypothesis depended on its explanatory efficacy for cases beyond the one for which the hypothesis was originally developed (Renfrew 1982). With the turn to post-processual archaeology in the 1980s and 1990s, concerns with the generality of hypotheses receded to the background. Adequate explanations, it was now theorized, had to attend to the uniqueness of each cultural context and to take account of the power and authority embodied in material culture and in the features of the landscape. They also had to pay attention to the human subject, now thought to be historically and socially situated, and, more crucially, to be capable of negotiating

the meaning of material culture and, at once, people's place in the social world (Thomas 1996; Hodder 1992). In discussing his "contextual approach," Hodder (1992, 14) also made it clear that the context of an archaeological object is "all those associations which are relevant to its meaning." Hence, the task of the archaeologist was to identify as many as possible of those associations, whether they could be traced in a single excavation trench or they had to be sought across a continent. Crucial aspects of the object's meaning might thus emerge and important features of the context's configuration might at last be explained.

In its insistence that explanations ought to explain the configuration of individual contexts (though not in its emphasis on the importance of meaning), post-processual archaeology reaffirmed the value of what archaeologists had already been doing and would continue doing in the new millennium. Today's scene is, however, very different from that of the late twentieth century. Researchers now adopt a more pragmatic attitude toward the objects of their research and are more concerned with obtaining sound results from their projects than with applying complex theoretical paradigms. They often revisit, for instance, old problems and enlist newly developed scientific techniques in exploring them. The reexamination and redating of the stratigraphic sequence at Arcy-sur-Cure, Burgundy, France, is a good example, especially since that sequence has long been considered crucial for appreciating the interactions of Neanderthals with Modern humans in Europe and, even, the symbolic capacities of Neanderthals (Hublin et al. 2012). The recently published research on ancient DNA extracted from the skeletal remains of Aegean and European Neolithic farmers also sheds light on a long-standing problem, the process of Neolithization of Europe. These and countless other recent studies are empirical throughout; they have clearly broken away from the theoretical quests of the previous century. Explanatory inferences now are increasingly based on the findings of the natural sciences.

It has long been recognized in the philosophy and praxis of science that theory is underdetermined by observation and, similarly, that observation is theory laden (see PHILOSOPHY OF SCIENCE; Wylie 2002). The underdetermination

thesis holds equally for explanatory inferences in archaeology, no matter how extensively they may draw on the findings of the natural sciences. Simply put, this means that more than one explanatory hypothesis may account for the same set of observations, though perhaps not all equally well. In theory, one decides among rival hypotheses by resorting to *abduction*, that is, inference to the best, or most plausible, explanation. Abduction is by no means a peculiarly archaeological form of reasoning. It is omnipresent in everyday thought and is also regarded by philosophers as a cornerstone of scientific methodology (Douven 2011). Like induction, abduction is ampliative: Its conclusions claim more than is logically guaranteed by its premises. Leaving aside the philosophers' conundrums concerning abduction, the practical question still arises, what makes some explanatory hypotheses better (more plausible) than rival hypotheses? Criteria for this are not altogether absent, but they are too abstract to serve as guides. For instance, a hypothesis that explains more observations is preferable to others that leave crucial observations out of account. But such a hypothesis may also be too general (it may explain too much) to be scientifically interesting. The inexact nature of criteria here may puzzle and dishearten the novice, but not the professional. For the latter, not impressed by the absence of sharply rational criteria, the process by which plausible explanations emerge is still a delicate, one but it has none of the mystique it entails for neophytes.

The expert indeed draws on a large stock of background knowledge relevant to the observables at hand, and his/her expertise consists in part of the ability to rapidly and more or less intuitively dismiss unpromising hypotheses and concentrate on others that deserve serious consideration. Some of the latter may be further corroborated, or weakened, by thought experiments and, further yet, by new empirical evidence. Thought experiments are ubiquitous in archaeological reasoning, but they normally reach the published page in an abridged form that does not readily reveal their hypothetico-deductive structure. An illustration of this practice is found in Arsuaga et al. (1997, 125) which pertains to the processes of accumulation of human and other mammal bones in Sima de los Huesos, Atapuerca, Spain, ca. 430,000 years ago. Were thought experiments of the kind to be analytically described,

it would become clear that they take the form of models from which expectations (E) are deduced, such that “if a hypothesis H is valid, then $E_1, \dots E_n$ should be archaeologically observable,” where $E_1, \dots E_n$ are likely material outcomes of the conditions specified in H . If those outcomes are disconfirmed by observations, the hypothesis is weakened; else, it gains in plausibility, even though, according to the underdetermination thesis outlined above, its truth will remain provisional and negotiable, subject to reappraisal upon further empirical research.

Reasoning through thought experiments is a typically rational way for reaching a plausible explanatory hypothesis. Its hypothetico-deductive structure brings to mind the “deductive-nomological” model of scientific explanation that was advanced by mid-twentieth-century logical positivists and was championed as an ideal by some archaeologists during the early days of processual archaeology in the 1960s. The two should not be confused, however: While the deductive-nomological model requires invocation of “covering laws” of nature (or culture), hypothetico-deductive thought experiments make no appeals to laws of any sort. They pertain instead strictly to local archaeological contexts, as do the explanatory hypotheses that emerge from them.

Parsimonious explanations, that is, explanations that rest on a minimum of assumptions, are intuitively more appealing than explanations that invoke a greater number of assumptions. In line with its intuitive appeal, in archaeology parsimony is invoked with remarkable frequency in support of one’s favorite explanation. Caution is needed, however: Archaeologists often use the adjective “parsimonious” in lieu of “plausible” or “satisfactory,” while “parsimonious” is at best a synonym of “economical” and “simple,” so that “the most parsimonious explanation” is in fact the simplest explanation (i.e., the explanation that depends on the least number of assumptions). In such cases, it is not clear that one’s favorite explanation is indeed the simplest of a set of rival explanations, nor is it clear that its alleged parsimony makes it more probable than the other explanations in the set. The main merit of a parsimonious and elegantly articulated hypothesis is their perspicuousness. But perspicuousness is a pragmatic virtue, not necessarily an epistemic

one; it does not by itself render a hypothesis more likely than rival hypotheses. In conclusion, it makes sense to bring parsimoniousness into the discussion *only* where two or more hypotheses explain the same set of observations equally well. Even in that case, parsimony and elegance of articulation can be thought of as methodological devices, not necessarily as justifications for ontological commitments.

Abduction in archaeology is by no means a value-free process. Entrenched beliefs about the moral order of the social universe, but also prestigious, broadly shared theories may limit the range of explanatory options in a given case by strongly favoring options compatible with themselves. The epistemic effects of such biases on the archaeologist’s inferences are by no means negligible (let alone their political consequences; see SCIENCE AND POLITICS). African archaeology of the colonial era, when Africans were believed to be incapable of self-improvement and all innovations in the continent had to be the work of colonists from elsewhere, is a well-known case in point. Comparable, if more muted, biases can interfere with archaeological inferences in the present as well. But today’s archaeology is characterized by an unprecedented plurality of voices and critical points of view, as well as by a fast pace of publication. In these conditions, biased inferences do not remain undetected for too long and their faults are critically appraised soon after they are published. Whether the future will be like the present in this respect is not clear.

Making and Skill

INA BERG

University of Manchester, UK

Making

On the strength of the Cartesian view that divides the world into nature and culture, the process of “making” is commonly considered to transform a natural material into a cultural object, an artifact. Practitioners hereby impose their desired mental design template upon the material world. In contrast, Ingold (1998) has advocated a “dwelling perspective” whereby the process of making is actually a process of growth in which maker, material, and the environment engage in an ever fluid and responsive act of co-creation. The form thus emerges out of the process of engagement or improvised journey, rather than being predetermined by an outside force. Practitioners themselves often refer to this intimate dialogue with the material as “feeling” (Keller and Keller 1996) and consider the material they work with as “alive.”

While tools are often utilized when “making” objects, it is our own bodies that are the original tools. On the one hand, the human body is a biological entity that functions in accordance with biological, anatomical, physiological, and neurological rules. Thus the way it interacts with its environment and with matter is broadly predictable and, some scholars would argue, almost preprogrammed. On the other hand, people learn to use their bodies in accordance with the customs of their society, and thus the body is an inherently cultural object whose movements and motor habits vary by age, sex, and class and from society to society. Instead of being *either* an exclusively biological *or* a social entity, the body is actually a biological, psychological, and social nexus—or, as Mauss would call it, an *homme total*. Culture-specific body styles such as walking, eating, or swimming are what Mauss has called *techniques du corps* (“techniques of the body”; see Mauss in Schlanger 2006).

While broadly in agreement, Ingold (1998) critiques Mauss for arguing that body techniques are acquired *from* a social setting, as if the environment contained a preconstituted concept of what is to be learned and as if that knowledge simply needed to be transmitted from one generation to the next. Instead, Ingold believes that nothing is transmitted just by itself but learning takes place *within* a social and environmental context, through a process of guided rediscovery. Acquired skills are seamlessly weaving together biology, evolution, and history as individuals grow up in their society. While focused more on environmental aspects, Ingold acknowledges the contribution of Gibson’s (1979) theory of affordances to his own thinking. Gibson’s ecological approach holds that motor habits are not being passed down as existing mental templates but emerge in a dynamic interaction between organism, environment, and task.

Ingold’s view is also related to Bourdieu’s concept of *habitus*. *Habitus* is a system of embodied dispositions that organize practices, thoughts, perceptions, and actions across a given group. The practices that constitute a *habitus* simultaneously reflect and reproduce a group’s or individual’s social history. “*Habitus*—embodied history, internalized as a second nature”—has a harmonizing effect; as individuals are socialized into their group, *habitus* is ever adapting and cannot be predicted (Bourdieu 1980: 56). These dispositions and practices are commonly shared and understood by members of the group and imbued with meaning, though this knowledge is not always declarative. *Habitus* relates to body postures or mannerisms as much as to mental classifications, feelings, and actions.

To the outside observer, the process that practitioners undergo as they make things appears to follow a linear sequence, which flows logically and uninterrupted from the beginning to the end of the making of an object. This idealized process is encapsulated in the term *chaîne opératoire* (operational sequence or chain). Introduced by Leroi-Gourhan ([1964] 1993), this methodology allows scholars to describe the step-by-step construction, use, and discard of

objects in chronological, spatial, technical, and sociosymbolic terms. Knowledge of all these aspects allows a structured, multifaceted understanding of practitioners, their craft, and the sociocultural context.

In reality, however, the act of making is neither linear nor necessarily fully thought through at the beginning. Producers usually have an “umbrella plan”—a concept of what they would like to produce and a skills set with which to achieve it. Interviews with practitioners have shown, however, that these ideas are often rather vague, with implications of actions and alternatives loosely interconnected and open-ended (Keller and Keller 1996). Practitioners experience the process of creation as a complex continuing reciprocal feedback loop as they compare the mental image with the actual reality, monitor their progress, diagnose problems, and apply corrective strategies. As the process unfolds, aspects that were important at the beginning fade away, to yield to entirely different features that are essential to a successful completion. Much of the manufacturing process and of the knowledge used in it are tacit, spontaneous, and automatic—what Schön (1983) has called “knowing-in-practice”—though it is particularly at points of failure that practitioners engage in more conscious reflection, revision, and correction.

Often practitioners across a domain develop a shared understanding of how tasks are to be done. Lave and Wenger (1991) have called groups that have a common interest in a subject, idea, or activity “communities of practice.” Communities of practice are united through the sharing of daily practice, learning, teaching, and knowledge that foster a common identity and meaning among members. This shared enterprise may be explicit, codified, and insitutionalized, but more frequently it is tacit, assumed, and embodied. Whether explicit or implicit, the resulting outcome of this common experience will be a shared repertoire of motor habits, styles, stories, tools, actions, and concepts.

As with the distinction between arts and crafts, scholarship traditionally separates between mind and body, assigning greater value to the former. When considering theories of learning, this mind–body dichotomy is most commonly expressed in a distinction between “knowledge” and “know-how.” Knowledge (*connaissance*) is

a mental representation of the object or process that can be passed on by means of words. By contrast, know-how (*savoir-faire*) is experiential learning that can only be acquired through doing. Knowledge is assumed to precede the know-how, since manufacture first requires a design. However, Ingold has persistently argued that one cannot separate the mental from the physical. Concepts and techniques can be communicated verbally and demonstrated physically. However, they cannot be taught as such. True knowledge and expertise can only be acquired through practice alone. Thus knowledge cannot be transmitted from generation to generation, but always has to be learned through practice: “the only way one can really know things... is through a process of self-discovery” (Ingold 2013: 1). This process requires the learner to physically practice the skill s/he wish to acquire. Practitioners have to gain experience in how something feels, looks, or sounds. This process of engaging practically with one’s craft is what Gibson (1979) has called an “education of attention,” also known as “understanding in practice.” Enskillment is hereby understood as learning by doing within the sociocultural context of the task.

Skill

According to Fitts (1964), skill acquisition falls into three stages of development: *cognitive*, *associative*, and *autonomous*. In the initial, cognitive phase individuals learn the fundamental structure of an activity. They are focused on learning how to execute the individual tasks and often can get lost in the detail (“tunnel vision”), but do not yet have an understanding of how these steps link together temporally or relate to the overall task goal. Tasks require great concentration, and mistakes are frequent. Feedback is essential in order to correct mistakes and misunderstandings. With repeated practice in the second, associative phase, learners gradually acquire the necessary individual skills and are able to execute tasks without gross errors. At this stage, learners are able to “chunk” activities into larger, meaningful segments, which can be completed more quickly and efficiently; and they develop a temporal understanding of the overall task sequence. An

understanding of how skills are connected to create the greater conceptual whole is now being developed. In the final, autonomous phase, performance has reached a stable and consistent level and the execution of activities has become almost automatic. Practitioners can now achieve a satisfactory level of performance effortlessly and rapidly. For most habitual everyday activities, it can take as little as 50–100 hours of training and experience to reach this level of competence. Research into typing and language acquisition has shown that competences, once gained, deteriorate only slowly and can be reacquired rapidly, even if a practitioner had ceased practice.

Feedback is essential if a learner is to improve. It can be verbal, physical, or both. Research has shown that a combination of verbal and physical instruction leads to the fastest improvements in the learner. This is often undertaken in a hierarchical sequence in which low-level skills are gradually combined into higher skills. When a teacher completes more difficult tasks that are beyond the skill level of an unassisted learner in order to allow that learner to achieve the final goal, the process is called “scaffolding.” That learning is an innately social activity is captured by Vygotsky’s (1976) concept of the “zone of proximal development,” where a child initially observes the teacher and then, over time, comes to work alongside him/her until s/he has mastered the task in its entirety. Lave and Wenger’s (1991) model of “situated peripheral learning” also places focus on how learning is more than task-specific skill acquisition; rather it includes the acquisition of social values and attitudes within which the skill is practiced. The knowledge of body techniques increases with age, as children observe and copy adults and internalize culturally appropriate behavior. Non-native learners, by contrast, are at a disadvantage because they, in effect, have to acquire two sets of skills. They will often require explicit instruction in order to learn how to move and position their bodies.

Following Ingold (1998), it is important to emphasize that skill is not something that can simply be passed on, like a formula or a set of rules, but has to be acquired by each individual, in a process of guided rediscovery that allows learners to grow them into advanced skills, to get a “feel.” Likewise, skill acquisition is biological

growth inasmuch as it is cultural growth, because the practitioner’s neurology, musculature, and anatomy change alongside his/her understanding of the cultural role and relevance of the skill.

Often practitioners are content with achieving an acceptable level of competence, though a few are sufficiently motivated to achieve the highest level of skill possible. Experts are individuals who have built up a large repertoire of possible actions and remedial interventions that are specific to their domain and that they can apply quickly and fluently to new situations and changing conditions as they actively monitor their performance. Thus expert performance is the exact opposite of automated or intuitive motor skills, or what Bourdieu has called “learned ignorance.” Research into chess, sports, medicine, computing, and music has shown that these outstanding perceptual, physiological, and cognitive capacities are not genetic, but acquired as a result of around ten years (or ca. 10,000 hours) of *deliberate* practice in a given domain (Ericsson, Krampe, and Tesch-Römer 1993). Deliberate practice has a different quality from regular mechanical activities in that it is reflective and targeted explicitly at improving specific aspects of an individual’s performance. It is most successful when there is immediate feedback and there are opportunities for repetition until the set goal has been achieved. Because deliberate practice is hard work and not inherently enjoyable, practitioners must be highly motivated and have an ability to concentrate fully, for up to four hours a day, when aiming to improve their performance. A high level of expertise in a particular domain is often sustained into old age, although normal age-related decline is apparent in unrelated activities.

Material Agency

ASTRID VAN OYEN

Cornell University, USA

Material agency denotes the possibility that things can act. The defining criterion for such agency has varied between theoretical strands, but generally entails the notion that material objects have an effect on the course of action that is irreducible to direct human intervention. The concept of material agency is part of the “material turn” that puts objects in the picture of the humanities and social sciences as more than simply passive instruments or empty shells for social symbols and meanings. It contributes to a broader challenging of the boundaries between ontological categories such as nature and culture, active and passive, or persons and things, and opens new opportunities for collaboration between scientific and interpretive archaeologies.

Relational agency

The notion of agency is an enduring legacy of post-processual archaeology. Moving away from New Archaeology’s template of people as survival- or profit-seekers, and infused with practice theory, post-processualism’s agency denoted people’s differential capacity to act, steered by their structural position, but allowing for the spark of contingency and improvisation. Gender, power, class, and so on were therefore no longer qualities that one possessed (as per New Archaeology), but emerged out of the constant, dialectical recomposition of social structure in daily practice and were inherently relational.

Post-processualism revolutionized archaeology’s take on human agency, but did not extend this to the object world. An interest in things as symbols (see MATERIAL SYMBOLS) was soon transformed into a broadly textual reading of material culture, emphasizing how things could be ascribed different meanings depending on

context. But not only are things unlike texts in many ways (see MATERIAL CULTURE); a hermeneutic model of “reading” material culture placed meaning and agency strictly in the human realm, far removed from things. Attributed meaning(s) by people, things themselves became passive signifiers in a semiotic play, defined by their arbitrary, contextual relation to other things, but not by their physicality, shape, or properties.

The material turn in the humanities and social sciences has invalidated this strict division between humans and things, between the social and the material. Ethnographers described how these divisions do not hold up in other societies, where there can be a fluidity between people, animals, and things, as in Andean cosmologies according to which the earth could solicit offerings or mountain tops could be revered as ancestors. Only in the last decades have anthropologists started taking these descriptions seriously as alternative ontologies, instead of merely classifying them as “premodern,” that is, on their way to transforming into a modern set of principles predicated upon a nature/culture duality. Meanwhile, ethnographers of science have muddled the supposed purity of the modernist scheme itself, by showing how scientific facts—the epitome of western immaterial rationality and its Enlightenment principles—rather than deriving from purely abstract eternal laws, are contingent upon such things as the size of test tubes, the distribution of funding, and the focus of gossip (see HISTORY AND SOCIOLOGY OF SCIENCE). This is not to say that science is untrue or unfalsifiable; it is rather to specify that its validity is built on foundations of a different nature and reach than previously imagined.

As the ontological fences were pulled down both by comparative anthropology and by close analysis of the western model, things and people started encroaching upon one another (see PERSONHOOD AND OBJECTHOOD). Things could be constitutive parts of persons, with cyborgs as the most evocative example. Conversely, people could not be truly social, or even human, without things: objects structure social interactions, and

enable many of the activities that make us human, such as writing, thinking, trading, and so on. But whether that means that things have agency and what this agency looks like is answered differently in different theoretical traditions.

Relational agency and the material turn

If agency is considered as something one possesses, then things tend to be denied agency. There does not seem to be something inherent to things that can make them act: things only act under certain circumstances, as part of particular assemblages, in specific settings. Material agency enters the agenda—implicitly or explicitly—only when the model of agency adopted is relational, situational, and dialectic. A first set of studies allow objects to contribute to action but refuse to label this as “material agency.”

Daniel Miller was one of the first to create conceptual space for things within a post-processual (or more broadly post-structuralist) framework of agency. According to Miller (2010), people come to understand who they are and what their position in relation to others is through producing and using things, a process termed objectification, nodding both to Marxist materialism and Bourdieu’s practice theory. Miller’s work has spawned a plethora of studies on consumption practices, taking as their object modernity across the globe: from blue jeans, over saris, to Coca-Cola. Objects feature in a humble yet important role, not only as the products or means of action, but also giving meaning and sense to those actions and their human agents. Yet material agency properly speaking remains dormant: things are either tools for (instrumental) or signalers of (representational) meaning. Miller’s model has sometimes been referred to as “materiality,” which has also, however, become a catch-all phrase for “objects.”

Recent phenomenological and cognitive archaeologies carry similar concerns of human perception and identity forward, but on a smaller scale. Phenomenology is one of the rare philosophical traditions of the twentieth century to have explicitly theorized the relation between humans and things. Heidegger’s tool analysis discussed how objects in our daily encounters

retreat into a kind of objectness in excess of human knowledge (ready-to-hand). The famous example of the hammer illustrates that this is only one possible mode in which people engage with the world: Only when hitting one’s hand instead of the nail does one realize that the hammer is really hard, solid, made of heavy stone, and capable of hurting (present-at-hand). Husserl similarly showed that our prime mode of apprehending the world is not that of scientific abstraction: When encountering a chair, for example, the chair can strike one as hard, comfortable, high enough to sit at a table, and so on, but not as “50 cm wide and made of polymers.” Others, like Merleau-Ponty, shifted emphasis to the human senses, which remained rather abstract in Heidegger’s accounts of human–thing encounters.

While phenomenology’s philosophical basis is firmly anthropocentric, it has provided fruitful grounds for the material turn. Philosophers and anthropologists of technology have built on phenomenology to demonstrate the inextricability of humans and things in the process of perception. Thermometers, for instance, actively make temperature readable and understandable to us—one might wonder how the notion of temperature would be different without them. And some people simply cannot see without glasses or contact lenses. These examples demonstrate the close collaboration of things in perception and experience, but things’ role can still be argued to be no more than a product of human instrumentalism.

The emphasis on perception and mediation puts this body of work in close conversation with recent cognitive studies that are moving away from a Cartesian tradition of studying the brain as a closed container, divorced from body and world. While phenomenology had initially been introduced in archaeology with post-processualism, cognitive archaeology was an offshoot of the processual tradition, as for example in Colin Renfrew’s theory (2001) that material symbols do not passively refer to pre-existing concepts, but instead were crucial in bringing new concepts (e.g., weight) into existence in human evolution. This illustrates how the material turn has helped make the old paradigmatic landscape of archaeology obsolete.

The body has emerged as a productive nexus for these issues of perception (see PERCEPTION

AND EXPERIENCE) and cognition (see MIND AND COGNITION), and has spurred another related branch of phenomenologically inspired studies on skill (see MAKING AND SKILL). Anthropologist Tim Ingold's work has been particularly influential in archaeology. His iconic example is that of weaving a basket: When one weaves a basket, one is not simply imposing a predefined mental design on passive matter. Instead, the shape of the twigs, their relative flexibility, their thickness, and so on, will all work together with one's hands and experience to produce the final form of the basket. In archaeology, this has provided a productive lens on crafts and embodied learning. While things—twigs and clay—have an effect on the course of action that is irreducible to outside forces, Ingold sees material agency as a reductive take on what is a constant flow of agency as more generic life forces across “meshworks” which can crystallize into stable forms, but only ever temporarily.

In all of the above strands, things contribute something to action that emerges in their relationship with humans. But whether for fear of losing humanity out of sight, or because of analytical strategy, humans remain the cornerstone of analysis and causality, and the term “material agency” is shunned.

Material agency

When “material agency” was coined as a term, it was in many ways no more than a rhetorical labeling of a concept that was already emerging in the material turn. Nevertheless, it generated shock waves within a long western tradition of human exceptionalism that is built into the moral, theological, legal, and social apparatus of contemporary society. In dissecting material agency per se, the below strands are less concerned with the minutiae of perception, skill, and material engagement than with causal effect.

Alfred Gell's *Art and Agency* (1998) breaks down sequences of actions into chains of cause and effect. The painting of a portrait, for instance, is not reducible to the intention of the painter and its translation to the passive matter of paint and canvas. Instead, the painter's intention is triggered by another art work or visual form. In

a similar vein, an art work can have a profound effect on its viewer, who is led to attribute agency to it deriving from the artist and the chain of precedents. As such, things are folded into causal chains whose driving force, however, still lies squarely with human action. The mechanical overtone of some of Gell's schemes of cause and effect—called *gellograms*—is the result of his reacting against the dominance of aesthetics in the anthropology of art at the time.

Aside from Gell's rethinking of the scheme of action and influence in art, he also offered a vivid reading of the human habit of anthropomorphizing objects. In defiance of our western ontology and its strict division between the material and the social worlds, we catch ourselves speaking to devices such as our cars, giving them names, and even attributing feelings to them. Gell remains firmly within western ontology, however, ascribing this anthropomorphizing phenomenon to a fallacy of human thought. While Gell created an opening for a material agency predicated upon causal effect, his work testifies to a continued struggle with anthropocentric models of agency.

The other framework that explicitly embraces an effect-based material agency is Actor-Network Theory (ANT). ANT originates in the social study of science and embraces a flat ontology as method by not a priori positing ontological parameters (e.g., active subjects, passive objects). Its proponents include Michel Callon, John Law, and Bruno Latour, and the latter in particular has provided a set of iconic examples perused in archaeology, such as the European hotel key. Latour (1991) explains the presence of key weights as the result of hotel managers trying to persuade their customers to leave their keys at the lobby desk when exiting the hotel. The key weight succeeds where oral and written requests failed precisely because of its material specificities—its size and weight. While at first glance the key weights may seem to be used instrumentally, to satisfy a human purpose, this does not capture their role fully: without the weights, this kind of action—persuading guests to leave their keys—would simply not have been possible. In the course of this process, the keys are no longer mere “keys” but have been transformed into something that is easier repeatedly picked up from the desk than carried around all day. In archaeology, ANT

has proven useful not just for rethinking the practices involved in the generation of archaeological knowledge (see *SYMMETRICAL ARCHAEOLOGY*), but also in understanding the creation of archaeological types, and in recasting actors and causes in large-scale historical narratives (Van Oyen 2016).

The most recent take on material agency to have been adopted in archaeology is assemblage theory, combining elements of ANT's radical ontological position with a notion of organic flows akin to Ingold and some of the phenomenological tradition. Gilles Deleuze is its main proponent, but in the meantime, assemblage theory has become a motley assortment of approaches, associated with theorists such as Manuel DeLanda and Jane Bennett (see *NEW MATERIALISMS*). All share a view of agency as distributed across heterogeneous assemblages, whose sum is greater than their parts. Assemblage theory holds particular attraction for archaeologists, because of its promise of accommodating scalar transitions; its emphasis on temporality as flows; and its affinity with archaeology's stock vocabulary of the "assemblage" (see *ASSEMBLAGE*).

The future of material agency

In sum: Things can have agency, but only if agency is seen as an emergent and relational phenomenon and not as an essential property; and this material agency is not just like that of humans. The most human-like material agency actually appears in those frameworks leaving least space for material agency, such as Gell's anthropomorphism. This is important to emphasize, as criticism of material agency and hesitation to adopt the term (as per the first set of approaches discussed) are rooted in a moral concern about equating things with humans. If not people, but guns, kill people (with Latour), then where does moral responsibility reside? While material agency does complicate the picture of causality and, therefore, morality, none of the frameworks above ascribes capacities of intentionality, reflexivity, and consciousness to things. Guns don't kill people *of their own decision*, but they nevertheless contribute an irreducible element to the final outcome of action. In that regard, John Robb (2010) distinguishes between a conscious

agency (why?), restricted to human agents, and an effective agency (how?), which is distributed and not a priori limited to certain ontological categories. In the end, then, the different versions of material agency are unwilling to abandon a western ontology. This is where the material turn diverges from the ontological turn.

While the moral and legal implications of taking relational agency seriously need thinking through, so does the model of causality that archaeology uses to write history from things. Things' agency is an effective, although not a determining, agency. It does not entirely discredit humans as the ultimate drivers of action, but it cannot exist but in a model of relational and emergent causality. This changes the configuration of possible answers to questions of "who" and "why." Ultimately, material agency may harbor its own obsolescence: As we grapple with the interpretive challenges it posits to the boundaries between humans and things, we may find that we are left not with things acting, but with different varieties of relationality and the challenge of characterizing those.

Material agency and archaeological sciences

Among the many unresolved issues surrounding material agency, three in particular hold promise for archaeological sciences, as already intuited by Andrew Jones (2004).

First, one type of critique from within the material turn, for instance by Ingold (2007), cautions against the under-theorization of material properties (see *SUBSTANCES AND MATERIALS*). In investigating just how the physical stuff of things contributes to their social effects, archaeological sciences can claim an important stake. Archaeology has a long tradition of attributing social and historical change to material revolutions, as in epoch-making transitions such as the Bronze Age. Material analysis, in turn, is foundational to archaeological sciences. More and more case studies detail the social dynamics of material properties, but these have not yet been abstracted to refine conceptualization of human–thing relations.

Second, how to project material agency in time? Through the analysis of provenance, recycling, and use wear, archaeological sciences have been instrumental in charting artifact biographies. But these are emphatically anthropocentric, modeling artifacts as having human life courses, and defining these with reference to external regimes of value. Ian Hodder's (2012) version of entanglement (see MATERIAL ENTANGLEMENT) instead shifts attention to the practical demands that things make on humans, drawing them into a bind of dependency, which has a temporal logic to it. Alternatives such as trajectories and genealogies can account for the unfolding of the social logic of broader classes of artifacts and their stylistic and material links. The challenge is not to portray matter as an inert substrate to the external changes undergone by objects.

Finally, the interpretive implications of material agency beg the question of how to marry the very grounding of archaeological sciences in the modernist ontological divide between nature and culture and its concomitant linear view of cause and effect with a big-picture emergent causality.

Archaeology and material culture

Material culture lies at the core of the archaeological endeavor to understand past and present societies. It is archaeology's precondition—if archaeology did not have material culture, it would have nothing to work with: no houses, no streets, no statues, no potsherds, no grinding stones. The past—and more recently also the present—is studied through the material remains of human activities, relations, and existential conditions, as traces and evidence of a wide range of topics. From very early on in the development of archaeology as an academic discipline, material culture has been the medium through which past human societies could be understood. Famously, Christian Jürgensen Thomsen (1788–1865) defined the Three-Age system on the basis of distinct materials of artifacts belonging to different periods. In the nineteenth century, material culture was the token of the evolutionary stage of the people behind the artifacts. The collection of Augustus Pitt Rivers (1827–1900), at the University of Oxford, founded in 1884, is a prominent example of this. The collection attempts to show the progress of human civilization, where simple artifacts are seen as a token of simple organization, while complex design marks complex societies. These are examples of how archaeology (and anthropology) has used material culture as a prism for understanding societies in the past and the present.

Yet, what constitutes material culture has nevertheless not always been agreed upon by archaeologists and anthropologists, and is constantly subject to differing uses and much debate. Material culture has been distinguished

in a number of ways, ranging from being synonymous with “physicality”—for example, a basalt statue—to being defined as the “sociality of things”—that is, as manifestations of cultural meanings through fabrication of material objects. A related concept is that of materiality, which may be described as the social constitution of self and society through things (Preucel 2006). Material culture is sometimes a collective denominator for a plethora of related terms and phenomena: technology, objects, artifacts, things, matter, aggregates, tools, stuff; each dominating another according to historical context or theoretical approach. For instance, Dan Hicks (2010) has argued that the term *material culture* only came to dominate after World War I, as an alternative to *technology*. Some scholars choose to define their terminology rigidly and distinguish clearly between, for example, artifacts and technology, while others opt for colloquialisms such as *stuff*, or use the term *material culture* without further theorization to denote something produced by humans. In this sense, material culture (e.g., a house) can be seen as in opposition to nature (e.g., a mountain). Yet such distinctions are often untenable. A hot-air balloon may be a case in point: People make the cloth (material culture), but it capsules air (nature), heated by fire (nature), ignited by people (material culture), all of which is transported by the wind (nature). Which part is material culture, and which is not, seems hard to distinguish. James Deetz (1977, 24–25) also noticed this when suggesting that even the way beef is cut is material culture, as it captures the cultural logics of what counts as ribs, tenderloin, sirloin, and so forth.

Most recent publications refer to material culture as a broad generic term, though, synonymous with archaeology's “matter.” So, while definitions are difficult and can be subject to debate, it is important to observe that “material culture” is composed of “material” and “culture.” This implies that culture is not necessarily material, and that archaeology is preoccupied with a particular dimension or expression of culture. It also indicates that not all material can necessarily be considered culture, and that

material culture refers to something made by, manipulated by, or reflected upon by humans. In recent discussions, anthropologist Tim Ingold (2007), in particular, criticizes the term *material culture*, as well as *materiality*, for divorcing “the material” from “the mind” (culture) as somehow hovering over things, rather than being integral in its continuous formation. Such critique is not lessened when terms such as *materiality*, which in other disciplines is considered to be raw unsocialized matter, is understood in some recent archaeology and anthropology to be inherently social (Miller 2005). There is no distinction between the social and the material, which is also what the combination of “material” and “culture” signifies to parts of the archaeological environment.

This terminological plurality is also reflected in curricula at universities, where courses in “material culture” can refer to different teaching outcomes. At some institutions, a course in material culture may build up empirical knowledge of the artifacts from a specific period (e.g., a comprehensive overview of Neolithic artifacts in southern Scandinavia), or offer an introduction to various classes of artifacts (e.g., flint, ceramics, or glass). In other educational institutions, a course in material culture might revolve around theoretical perspectives on material culture as a means of understanding societies and relations in the past (e.g., to understanding power, gender, rituals, or economy). Material culture may thus refer to rather different fields of knowledge and to disparate academic frameworks for understanding archaeological sources.

Hence, material culture in archaeology has two roles: First, it works as primary archaeological source material; it is the stuff through which archaeologists can access knowledge of the past. And second, it works as a medium for social relations; it is one of the media through which people forge relations, negotiate power, and construct their identities. The first of these roles implies that material culture is archaeology’s data, and the second indicates that these data need to be processed in order to constitute knowledge of the past in meaningful ways.

The social role of things

The latter role of material culture—its capacity for constituting relations between people, whose bodies may itself be seen as material culture, and between people and the material world—has been the primary focus of attention in archaeology since the mid-late twentieth century. Walter Taylor (1913–97), for instance, argued that culture was not observable to archaeology directly, because culture was located in the mind, yet material culture is the product of culture, available to archaeological scrutiny. A number of archaeologists also became concerned with how the relationship between culture and artifacts was to be understood, and wanted to understand the structuring effects of material culture in the development of a certain cultural behavior. This led to the proposition that artifact design, and the use and distribution of artifacts, could be seen as patterned, and that the pattern reflected a given cultural behavior: the socialization and implicit cultural norms behind the archaeological assemblages. For James Deetz (1930–2000), it was important to observe how these patterns changed over time, and how they could be traced archaeologically. Lewis Binford (1930–2011) famously defined culture as the extra-somatic means of adaptation, which means that material culture is basically a means of survival for the human organism. However, he dismissed the idea that archaeology had the objective of studying the relations between human behavior and material culture, since he maintained that the archaeological record does not hold any direct information on that topic. Binford argued that the cultural “system” producing the archaeological record was fundamentally different from the record itself: There is, in other words, no *direct* correlation between excavated material culture and the society originally producing these artifacts. Instead, archaeological assemblages had to be correlated with comparative uses and distributions of artifacts in living, “dynamic” contexts in order to unlock the archaeological record. Binford also argued for an empiricist and quantitative research design, which was mirrored by other influential scholars of his time, such as David Clarke (1937–76) and Colin Renfrew (born 1937), both at the University of Cambridge.

Along these lines of research, Renfrew has been a key proponent of the pursuit of a cognitive archaeology to study the relationship between the human brain and behavior through skeletal evidence and material culture.

Archaeological redirection formed in Cambridge as a response to the positivist and scientific agenda of the above approaches to archaeology and material culture. This has marked the beginning of the most dominant approaches to the study of material culture in recent years, building on the work of Ian Hodder (born 1948) and the so-called Cambridge School in the early 1980s. This agenda has also been called “the material culture turn” or “the material turn.” This approach revolves around understanding the *active* nature of things in social life. That is, objects do not merely *reflect*, but help *constitute* identity, power, gender, and so on. Hodder wanted to understand the continuously changing role of things and the symbolic meanings they carried. He and his students thus explored the potential of understanding the active role of material culture in human life, including ethnoarchaeological studies in the present. The ambition to explore identity and power through material culture was in part represented by the development of a distinct gender archaeology. The focus on gender provided a framework for examining the relationships between body, embodiment, identity, and the engendering of material culture. Moreover, this included important steps in the direction of analyzing not only the ways in which objects are associated with gender, but also how gender is shaped through material and corporeal performances.

This intellectual background, along with many of the students graduating, led to the formation of a more disciplinary independent approach to material culture, which in the British context, in particular, centered on Daniel Miller (born 1954) and Christopher Tilley moving from Cambridge to the anthropology department at University College London (UCL). Miller and Tilley focused on what Miller calls “processes of objectification,” where the key point is that people continuously shape their values and meanings through material culture, which in turn shapes their lives. Even the things we rarely notice are part of processes of constituting social worlds by acting in the background, not as separate reflections of said

values, but in a constant dialectic between subject and object. Key topics here have been the practices that people do with objects, how things are transferred from a market sphere to a personal sphere, and how phenomenological perspectives on things may open new understandings of the role of things.

Another simultaneous discussion was seen in a focus on “the biography of things” in the wake of Igor Kopytoff’s (1930–2013) article in the influential volume *The Social Life of Things* (Appadurai 1986). Here, objects, like people, are shaped by the history of use and meanings they have taken part in, and thus, like people, must be understood through a biographical lens. An object is, thus, not just an object, but is formed by the relation of which it is a part. A product of this more general call to understanding material culture as an essential part, rather than merely a passive product, of social life, is the cross-disciplinary *Journal of Material Culture* emerging from the UCL research environment.

As indicated above, much of the discussion of material culture in archaeology is found in its dialogue with anthropology. One such example is the heated debate at the turn of the twenty-first century around what Alfred Gell (1945–97) calls “the agency of things” (Gell 1998). Here material culture is seen as an agent in social lives, although not with the same capacities as humans. A marked shift here, which is still intensely debated, is the switch from seeing agency as resting on *intentionality*, where material culture cannot choose to do otherwise, as humans can, to *causality*, where agency is what causes an event to happen. For instance, it is the agency of the flames that makes a house burn. But there may be multiple agencies involved in the process, depending on whether it was lighting it that made the fire to begin with, or a person lighting matches who ignited a material that fell on another highly inflammable object that then set the house on fire. In such discussions, we thus see, in the most profound way, the distinction between material culture as the (passive) outcome of human practices and the (active) role that objects, whether tangible or intangible, play in human practices.

Although covering many different perspectives, the most dominant branches of material culture studies originated in the 1980s, in what might, in hindsight, be dubbed, respectively,

the Cambridge School and the UCL School. It may not be entirely unjustified to speak of the recently formed “Stanford School,” which is largely synonymous with so-called symmetrical archaeology. Symmetrical archaeology was largely formed as a critique of modernist “bifurcations,” that is, the perceived dualisms between humans and objects, nature and culture, and past and present. Scholars such as Michael Shanks, Christopher Witmore, Timothy Webmoor, and Bjørnar Olson (2012) argue that archaeology is fundamentally *the* discipline of things. They borrow their vocabulary from anthropologist Bruno Latour, and speak of the “infiltration” of humans and nonhumans, which means that humans are not distinguished as being of primary importance in the archaeological endeavor. Instead, the human is de-centered and assumes a position as a phenomenon among many other heterogeneous phenomena. Rather than speaking of material culture, these scholars furthermore choose to orient their terminology towards “things” or simply “nonhumans.” In this, they draw on the notion in Martin Heidegger’s philosophy of the *thing* as etymologically coming from the verb *to gather*. This implies that things have the capacity to constitute gatherings of a variety of phenomena: social meaning, identity, function, symbolic value, and so forth. In this capacity, symmetrical archaeologists argue that we need to see humans and nonhumans as a continuity that should not be parceled out rigidly, because even though people and things are different (as are all people and all things), they are not oppositions. We have thus, since the 1980s, seen a strong move to redefine the term *material culture*, or simply shift to another word, such as *things* or *materiality*, even turning back to *technology*, the word that predominated in the nineteenth century.

Future directions

The embedded nature of material culture and human lives is now evident, and the necessity for interdisciplinary collaboration to explore such entanglement has proven its point in archaeology. Although the ever-increasing new methods to understand aspects of material culture offered by natural sciences have prevailed, so too have theories from disciplines such as anthropology,

geography, design, sociology, and art history shown their value in understanding what things mean, do, and symbolize, questions that have framed material culture since the 1980s.

To highlight some trends we see expanding at the time of writing, it is first clear that the advances made in natural sciences and technology will undoubtedly shape the future of understanding material culture, and the social worlds it has constituted in the past. While the specific questions asked often say more about the contemporary period than the past, ancient DNA studies have, for instance, allowed for new insights into the demographic composition of regions, and hence also highlight trade routes and innovation processes shaping material forms. In archaeological topics like these, we see a pivotal role in bringing science and archaeology closer together. Likewise, the use of drones and digital maps has expanded the possibilities of finding new locations and areas of ancient cities that have hitherto gone unnoticed. In essence, such techniques allow us to understand broader global issues of origins and the movement of people, things, and ideas, while also democratizing the exploration of material culture to encompass both highly specialized DNA scientists and amateur drone users and Internet explorers. Simultaneously, isotope analysis, micromorphology, use-wear analysis, and other such techniques offer insight into everyday life, perhaps even individual life stories, in combination with DNA records, of people long past. In other words, with the developments in new technologies and material sciences, we are able to correct previous knowledge by asking new questions of the material remains about human origins, organization, and spread.

Second, archaeology, beyond the exploration of the past, offers a critical perspective on the present. This is particularly achieved through the increasing focus in archaeology on dissolving radical distinctions between past and present in intellectual currents such as “critical heritage studies,” exploring the political entanglement of places and past material culture in the present. In such a context, the role of archaeologists—to engage with popular or alternative conceptions and imagery about the past, as unfolding through material remains—is pertinent, although still in pressing need of more intellectual and theoretical

debate. Archaeology and the study of material culture thus has become an increasingly intellectual endeavor as much as an exploration of the past. It appears that while academic careers are often made from excavating new locations, it is important also to more actively engage with both the publication and interpretation of earlier finds, not least in the way they play a role in contemporary heritage politics (Smith 2006; Harrison 2013).

Finally, the limits of relying on available material culture have become evident. Not only are archaeologists often left with very little material to make claims from, often there is actually a socially productive deliberate avoidance of things either on individual, community, or political scale—incandescent light bulb and smoke bans are contemporary examples. For instance, as Severin Fowles (2010) illustrates, taboos as well as restrictive consumption ideas may foster a lack of material culture, which is central to an understanding of said past society. One strand of future directions may thus point towards exploring how and why things are or become absent. Parallel to this is also the fact that people's sensory experience is shaped by intangible material culture, such as light, smell, and temperature, or by other less tangible material forms, which are only more recently being investigated as a form of material culture (Bille and Sørensen 2007; McFadyen 2010).

Material Entanglement

IAN HODDER

Stanford University, USA

Colloquially the word entanglement is used with many inflections of meaning. Dictionary definitions usually refer to a mass of confusedly interlaced or intertwined threads or strands, knotted or coiled together. People talk of being snared in entanglements that are complicated, unfortunate, or obstructing. Entanglements seem like jumbles that are difficult to sort out.

For example, US relations with China are described as entangled because on the one hand the United States and China want to reach agreement on climate change (for a whole set of perhaps quite divergent reasons) and yet they strongly disagree on human rights, on technology copyright, on hacking, and so on. So a key idea is that entanglement involves contradictions. The latter cannot be described in terms of positive and negative feedback, and they cannot be reduced to Marxist contradictions and dialectics. Rather, the general condition of life is that all complex phenomena contain operational chains that contradict each other.

Out of these daily uses of the terms tangle, entangle, and entanglement, there seem to be four key inflections of meaning that will also be seen to be present in scholarly debate about entanglement theories: (1) Entanglements involve a mass of strands. It is not enough to focus on a few variables at a time, or to make mono-causal arguments. Rather, it is necessary to explore the multiple threads and to pursue their heterogeneity. Entanglements are assemblages in which there are components and linkages of many types (material, social, economic, symbolic, etc.). (2) These different threads are often in contradiction with each other, as the example above indicates. (3) The threads are in such a mess of jumbled knots that it is difficult to sort them out as an analyst, and it is difficult to extricate oneself as a social actor. There is the idea of being

caught in a snare or trap. (4) As a result of the other three factors, problem solving is hampered or obstructed such that movement forward is channeled. There is path dependency.

The notion of entanglement has been used in a wide variety of scholarly debates. In biology there is often reference to the famous phrase at the end of *On the Origin of Species* where Darwin writes: "It is interesting to contemplate an entangled bank, clothed with many plants of many kinds, with birds singing on the bushes, with various insects flitting about." Many developments in biology focus on coevolution and symbiosis between humans, plants, and environments. Indeed, recently authors such as Evelyn Fox Keller have discussed a new Extended Evolutionary Synthesis in which culture and genes are not seen as separate forms of transmission but able to enter into each other through epigenetic and other processes. Culture and biology are thus thoroughly entangled. But perhaps the field in which entanglement has most influence today is in quantum theory in physics, where entanglement describes the mechanical phenomenon in which the quantum states of two or more objects have to be described with reference to each other, even though the individual objects may be spatially separated. This implies that the movement of an object cannot be predicted by reference to local conditions.

In philosophy, the work of Deleuze and Guattari has long been influential in moving away from hierarchical systems of classification and origination, and emphasizing the rhizomic links that flow between entities. Rather than searching for origins and hierarchies of causes, the focus is on the complex ways in which things are caught in webs. In anthropology and the cognitive sciences there has been a strong focus in recent decades on the ways in which perceptions and notions of self are distributed beyond the physical body. For example, Marilyn Strathern has talked of enchainment or distributed personhood. The term "enchainment" as used by Strathern refers to Polynesian and Melanesian cultures where persons are "dividuals" or "partible persons"—that is, persons are the products

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

DOI: 10.1002/9781119188230.saseas0365

of chains of socially reproductive acts, so there is no division between the social and individual persona. Other approaches in anthropology have explored different ontologies. For example, Descola has described four different ways in which the relations between humans and animals are construed in different societies: animism, totemism, analogism, and naturalism.

Taking us closer to the notion of material entanglement are the many approaches that have described colonial encounters in terms of the ways in which communities get caught up in each other. In her work on contemporary South Africa, Sarah Nuttall describes the historical entanglements between blacks and whites. The more whites dispossessed blacks, the more whites depended on blacks (for labor) and the more blacks depended on whites. In their dependence on blacks, whites erected an ideology of separation and difference—racism. In effect, Nuttall describes a co-dependency. She problematizes simple oppositions between colonizer and colonized, metropole and colony, center and periphery, domination and resistance. She talks instead of an entanglement or “web, carrying with it the notion of interlacing, an intricacy of pattern or circumstance, a membrane that connects.” More influential for the work of archaeologists has been the work of Nick Thomas (1991) who writes of western and nonwestern peoples “mutually entangled in an array of rights and obligations, people who are ‘reciprocally dependent’” (Thomas 1991, 14) in the exchange of objects in the processes of colonialism. “The notion of entanglement aims to capture the dialectic of international inequalities and local appropriations” (Thomas 1991, 207). Rather than opposing European and indigenous, global and local, capitalist commodity and reciprocal gift, domination and resistance, Thomas’s work has influenced archaeologists studying colonial interactions (such as Dietler, Gosden, Jordan, Orser, Silliman, and Stein) in order to attain what Martindale describes as “a more historically accurate consideration of the complexities of the colonial encounter.”

While direct discussions of entanglement in archaeology are often influenced by the work of Nick Thomas on “entangled objects” there is a broader influence from studies of material agency and materiality. Since the 1980s, many

archaeologists have followed the work of Pierre Bourdieu on theories of practice and have argued that material culture can be actively employed in social strategies rather than being a passive behavioral response to adaptive conditions. The study of material culture (Miller 1987) and materiality (Meskell 2008) has had much impact on the ways in which archaeologists study humans as agents and things as agents, and there has been a lively debate on what the notion that things can be agents might mean. One of the outcomes of this discussion has been a critique of social theories in which humans are central, without things playing a major role. There has been discussion of a relational archaeology (e.g., Watts 2014) in which identity and causality are seen as dispersed, and there has been the claim for a symmetrical archaeology (Olsen et al. 2012) in which equivalent weight is given to humans and things.

The calls for a symmetrical archaeology have a more direct source of inspiration in the work of Bruno Latour. The study of socio-material networks by Latour has also had a very direct influence on material entanglement approaches in archaeology, although we will see below that the notions of network and entanglement are very different. Sociologists have tended to see the social world as about interpersonal relations. But Latour, Law, and Knorr-Cetina have come to see how engines, measuring instruments, laboratory probes, and detectors play a part as actors in structuring social relationships. These authors explore the production of scientific knowledge in the laboratory, but they also argue that similar social/thing processes occur more widely. They focus on the actor networks of big things like the French computerized rail transportation system called ARAMIS (Latour 1996), but they also look at small things like pipettes, paper blueprints, computer screens, and so on. The aim of this type of approach, often termed Actor Network Theory (ANT), is to focus on relationality rather than on apparent fixed and essential dualisms such as truth and falsehood, agency and structure, human and nonhuman, before and after, knowledge and power, context and content, materiality and sociality, activity and passivity. It is not that there are no such divisions but that the distinctions are effects or outcomes. As Law states, “They are not given in the order of things.” Thus, ANT

conducts a “semiotics of materiality.” It takes the semiotic focus on relationality and applies it to all materials, producing a relational materiality.

Other approaches focus more on flows and meshworks. For example, Tim Ingold (2010) places more emphasis on the ways in which humans and things co-construct each other in the practices of making. He explores how things are always changing in relation to humans and their perceptions. Environments are landscapes that are lived in and moved around, a pebble is different depending on whether it is wet or dry, a basket emerges out of the interactions between reeds and humans as it is made. Karen Barad has developed a theory of agential realism in which objects do not just exist and then interact. Rather they emerge through their “intra-actions.” Because everything is so entangled in everything else, when we observe something we have to make a “cut” that includes and excludes, so that the boundaries of entities are always temporary constructs. In reality, there is no interaction between separate entities, only actions within the whole, intra-actions.

A similar set of moves can be discerned in the archaeological accounts of material entanglement. Archaeologists have long studied the material properties of things, and the subfield of archaeometry has been devoted to chemical, physical, and biological techniques for understanding how material things were made and used and discarded. There has also been extended study of the operational sequences by which things are procured, manufactured, used, and thrown away. The main approaches have been of *chaînes opératoires* in the French tradition as described by Leroi-Gourhan and Lemonnier and behavioral chains in the American tradition as discussed by Schiffer. While these approaches have, in their different ways, been very effective at unpacking the ways in which material things can be studied, they have been less effective at developing a theoretical framework that links them to the social world. Things are largely seen as objects of human action rather than as co-constituting the social.

Material entanglement approaches in archaeology result from a critique of anthropocentric approaches but also from a critique of networks. For example, I have defined entanglement in terms of four types of dependency (Hodder

2012): how humans depend on things (HT), how things depend on other things (TT), and how things depend on humans (TH). If we add the obvious point that humans depend on humans (HH), then entanglement, at one level, is simply the addition of these four sets of dependences and dependencies.

$$\text{Entanglement} = (\text{HT}) + (\text{TT}) + (\text{TH}) + (\text{HH})$$

The defining aspect of entanglement with things is that humans get caught in a double bind, depending on things that depend on humans. Put another way, things as we want them have limited ability to reproduce themselves, so in our dependence on them we become entrapped in their dependence on us. Thing dependence on humans entraps humans into investment and care. But this is only because humans are so utterly dependent on things in the first place for all their physical and emotional and cognitive needs, and it is amplified because things depend on other things.

Within this definition, rather than simply identifying links in a network, attention is paid to the complex relations that comprise those links. In particular, a great load is placed on the term “depend.” There are various inflections of meanings in this word. On the one hand, dependence means reliance; it also has a contingent notion as when one says “it all depends.” On the other hand, dependence or dependency involve constraint, as when two people are in a co-dependent relationship that is mutually destructive, or as when colonial powers constrain the development of the colonized (see above). Thus, another way to define entanglement is to say that it is the dialectic relationship between dependence, often productive and enabling, and dependency, often constraining and limiting. Humans and things, humans and humans, things and things depend on each other, they rely on each other, produce each other. But that dependence is in continual tension with boundaries and constraints as things and humans reach various limits (of resources, of material and social possibility) that are overcome by, that demand, yet further dependence and investment. Entanglement can thus be defined as the dialectic of dependence and dependency between humans and things. Within the networks and flows there is a “caught-up-ness.”

However, it is difficult to hold fast to these initial definitions of entanglement as the sum of HT, TH, TT, and HH dependencies and their dialectical relations. Such a characterization appears to separate subject and object, culture and nature, in ways that have long been critiqued. Human being is always already dispersed and distributed into the world; there is no environment separate from human culture and society. It is thus difficult to talk of TT dependencies without human involvement, or of HH dependencies without things. Separating out TT, HH, TH, and HT dependencies from overall entanglements is difficult. A more satisfactory definition of entanglement accepts that entanglement is but a metaphor. It is a metaphor that tries to capture the contradictory messiness of the heterogeneous flows and counterflows that produce, enchain, and encompass entities (humans, animals, things, ideas, social institutions).

One technique that can be used to study entanglement is formal network analysis. “Tanglegrams” can be drawn that show all the dependences and dependencies between entities in a field of interest. This approach is very effective at exploring the multiplicity of links between entities and it is good at helping to define hubs and concentrations within the overall messiness of entanglements. It is less good at exploring the nature of the links between entities, the dependence and dependency, but other forms of quantification can be used here (Hodder and Mol 2015).

Another applied aspect of entanglement theory is the study of path dependency through time. Because the links between nodes in entanglements are so complex and heterogeneous, and because humans become invested in things, it becomes difficult to change paths. Changing one thing has so many effects on other things that there is constraint in moving forward. It becomes very difficult to move backwards and disentangle. A good example is provided by the work of Dorian Fuller (Fuller, Allaby, and Stevens 2010) who has shown how the genetic changes that produced domesticated plants resulted in the plants becoming dependent on humans for their propagation. There were advantages for humans in using domesticated plants: they provided more food per unit of land. But, on the other hand, humans became trapped in extra labor—the threshing and winnowing required in order to

release nutrients from domesticated grains. Once this step had been taken, it was difficult to go back. There are societies that move back and forth between farming and hunter-gathering, but in many parts of the world the dependence on domestic crops led to numerous other changes such as larger settlements, more complex social systems, larger ritual monuments, and greater trade. Once all this had been entered into it was difficult to return to a hunter-gatherer way of life; humans had entered a pathway that was difficult to reverse.

Another example is provided by the adoption of pottery in the Neolithic of the Middle East. In the initial stages of pottery use at the site of Çatalhöyük, the main use was for food serving. Through time, the affordances of pottery became realized and the entanglements of pottery increased to include cooking and then storage and social display. In the initial stages of this process it would have been relatively easy to stop the dependence on pottery, but as the entanglements increased, “points of no return” were reached so that it was difficult to give up and disentangle from pottery.

In conclusion, it is often said that the study of material entanglement has a negative hue, imparting a sense of being trapped in pathways that lead in specific directions. Part of the attraction of the term may be that it resonates with a wider global sense of being trapped. Increasingly we seem met by intractable problems such as global warming, or the gridlock of international agencies such as the United Nations that seem powerless to act, or by the inability to introduce gun laws in the United States despite repeated mass shootings. In terms of food consumption, we are trapped in the nonsense of throwing away large amounts of the food that is produced; and campaigners such as Alice Waters argue that we are imprisoned in fast food, leading to obesity and a high incidence of diabetes. In small and large ways, we seem increasingly stuck. These everyday senses of being cornered and unable to find a way out are perhaps what provide entanglement its traction in the contemporary world.

On the other hand, it is important to stress that archaeological studies of material entanglement also allow exploration of how a particular present and a particular notion of human and of thing have been produced. The approach is

fundamentally historical and particular, and it demands exhaustive analysis of the complexity of human–thing relations in all their specificity. It allows archaeologists to explore how humans entered down pathways that produced global warming and other contemporary predicaments. It allows us to understand the full complexity of the problems in cases where entrapments were entered into millennia ago. But it also encourages us to ask whether there are fundamental alternatives. After all, if humans are only humans within their entanglements with things, then it must be possible to conceive of other forms of dependence in other worlds of things. It must be possible to “be human” and to “be a thing” in other ways.

Material Metaphor

KEITH RAY

Nexus Heritage, UK

In linguistics and literary studies, metaphor is widely understood as the application of a name or descriptive term to an object, person, being or situation to which it is not literally applicable. As such it is a communicative trope, and its purpose is to invite novel appreciation of a quality or qualities that are familiar from the source object to the subject object concerned. The key differentiating characteristic of metaphor, which distinguishes it from simple substitution such as occurs in metonymy (wherein the name of something is used in place of naming the thing itself: as in the use of “the crown” for “monarch”), is that it involves *transformative* comparison. So although a metaphor may at root be metonymical, in its deployment in discourse it travels further. As such, it intensifies the effect of such comparison not only by reproducing accepted meanings, but also by creating novel ones.

Anthropologists have identified metaphor as permeating the cultural representation of social experience and as being used actively in the structuring of discourse, for instance via the use of animal categories as a key source of analogy. Such classification is not, however, the result simply of cognitive norms or ordering devices. Rather, it is motivated: metaphor is central to social strategies involving the construction and sustaining of individual and group identities, inclusion/exclusion, and so on. In particular, ritual activity has long been identified by anthropologists as a key locus for “social metaphor” deployed strategically. For example, the Fang cult of *Bwiti* has been seen to exemplify two crucial aspects of such metaphorical usage. One is that metaphor not only expresses “cognitive mapping”, but also structures it. The second is that this structuring is achieved by drawing upon the parallel capacity of both metaphor and ritual to produce dramatic shifts in understanding. So,

for instance, ritual events can employ linguistic metaphors of transformation while the ritual process itself is metaphorically transformative.

Meanwhile, there has been much debate in English, as in other languages, as to whether all human thought and language is in fact metaphorical. It is possible, according to George Lakoff (1993) and others, to regard metaphors as models for understanding the world, and therefore as fundamental to cognition. The danger that has been noted about such an all-embracing understanding of what metaphor comprises is that it may bring into doubt whether any distinction is possible between literal and metaphorical statements. However, whatever are the broader metaphysical implications of linguistic or literary expressions involving transformative comparison, it is the use of metaphor primarily as a device deployed strategically in social discourse that has the greatest potential for identifying and exploring the way in which social relations and social structures are sustained and reproduced in dialogues within and between the verbal, literary, and material domains.

There has not been a long history of the discussion of the relevance of metaphor, and metaphor theory, to archaeology. The first published use of the term “material metaphor” appeared in 1987 (Ray 1987, 67; cf Preucel 2006, 142–143), but while the relevance of metaphor to archaeological inquiry has been noted both implicitly and explicitly in a number of archaeological writings (see below), there has been little extended treatment since then. In the only book-length discussion of metaphor and material culture published so far, Christopher Tilley (1999) identified many examples from cultural anthropology and ethnography of how, in pre-industrial societies, the natural world, animals, and the inherited environment provide a rich source of metaphors that is referenced materially and expressed durably through the creation and deployment of artifacts expressive of the relations concerned. It is thus the “coded” visibility of specifically *material* metaphor (Tilley used the somewhat misleading term “solid metaphor” interchangeably) that

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

DOI: 10.1002/9781119188230.saseas0366

makes it such an effective communicative device. Tilley referred to one particularly vivid example of this process in action from John Layard's 1930s researches among the peoples of northern Malekula in Vanuatu. Here, four categories of boar were recognized according to the stages of growth of their tusks. These categories were mapped against the passage of time through the lives of the men who had raised the boars, and their sacrifice was implicated in the rich field of symbolism and metaphor that linked the biographies and reproductive lives of both men and women (Tilley 1999, 53–54).

Meanwhile, in other Pacific Ocean contexts, canoes have been noted by field researchers as implicated in social relations and discourse in reference to the human body, and especially to orifices and openings, and states of being. Elsewhere in the world, these bodily references have been carried over into other aspects of technology, such as ironworking, and into descriptions and uses of portable items such as baskets and axes. Working back the other way, archaeologists focusing upon ancient contexts have sought to interpret patterning in, for example, the treatment of corpses and what was included in burial assemblages (cf Bruck, 2004, in reference to Early Bronze Age funerary contexts in southern Britain), or in the orientation of the doorways of circular huts, as evidence for the metaphorical evocation of social relations or body parts (or both). The impact of the transformative nature (via kilns and furnaces) of both pottery manufacture and metal-working in Bronze Age Europe has, meanwhile, been explored in terms of its metaphorical associations (Barber 2003, 165–170).

The efficacy of metaphors, whether material or verbal or literary, is greatest where a transposition of form draws sudden and unusual attention to a transformed condition, or relationship. In verbal discourse, this is achieved through placing two entities not simply into contrastive, but into actively incongruous, relationship to one another. In nonverbal discourse, the creation of an object in a familiar form but in another material—that is, in the practice of *skeuomorphism*—most graphically draws attention to the compared entities, and potentially carries the association of the “source” form into new contexts. Where this transformation and translation has involved the creation of a more durable version of an object in an otherwise

perishable form, it enables archaeologists to learn about the form of the “source” item irrespective of whether the organic artifact has survived, for instance in waterlogged deposits. While this can provide a more complete picture of the past material culture of the relevant society, it is not the sole interest archaeologically. This is because the question of the motivation to have made and deployed the *skeuomorphic* item in the first place is at least equally important. So, if for example the labor and economic power of women in marketing is habitually referenced by their making and using baskets, the *skeuomorphic* transposition of baskets into pots may render this economic role both more visible and more durable. The creation and deployment of *skeuomorphs* of a range of objects including baskets, calabashes, wooden stools, and title-staffs at tenth-century CE Igbo Ukwu in southeastern Nigeria was in this way highlighted in order to suggest that a series of abstract concepts and excluded persons and actions was brought into presence in a context (the ritual store-house of a senior male lineage group) where some or all of these practices and persons may “normally” have been excluded (Ray 1987).

Tamara Bray (2008) has meanwhile noted how Inca elites created a specific set of fine and highly figurative ceramic vessels which through their decoration metaphorically referenced clothing that was prescribed for use by the social group concerned. It proved possible to explore the depth and breadth of allusion involved in this decoration in reference to ethnohistoric evidence for the ordering of Inca society. A metaphor of “containment” was expressed through painted images of particular kinds of cloth on the sides of highly elaborated pots. These cloths were those used as clothing wrappers by the elite members and so the pots served as the (literal) embodiment of the prescriptive codes of practice and aesthetics concerned. Such prominent symbolization in effect appropriated the domain of the domestic to the elite and naturalized the social stratification that maintained the structures of dominance and subordination that had developed in the Bolivian Andes.

If the motivation for the creation of complex “material metaphors” can in many cases be seen to have been strategic or negotiated, it is also important to assess why a particular density of such co-referencing may have taken

place at a particular place and time. So while at tenth-century Igbo Ukwu a key motivation to such density of allusion was surely to reference the power of whomsoever had commissioned or “consumed” such materials, other reasons for the extravagant use of resources to create the extensive assemblage of elaborate metalwork (in particular) were detected. One such purpose was to mark a key historical juncture at which a series of abstract concepts, associations, and social relations (especially and specifically around power) were made “concrete,” both conceptually and materially. This juncture was connected with the amassing of wealth through trade, exemplified by the presence of ivory elephant tusks and of masses of exotic beads. Some particular associations were understood as constituting “historical metaphor.” In the first place, a “foundation myth” for the origin of agriculture and the development of a sacralized leadership system locally was cited in the representation in bronze of an oral tradition concerning an act of sacrifice of the “first” male and female offspring of the mythic lineage founder. This act was said to have brought food to the Igbo: and the enactment of skin scarification symbolically recreating the farming furrows denoted membership of the privileged foundational lineages. The second was through the “choreography” of a particularly richly furnished grave of one of the ritual leaders themselves, which referenced the ceremonies of both symbolic and actual death and rebirth associated with the holding of a particular lifetime-only leadership role. The manner of placing of the body in an upright position, supported by staffs, and sat on a stool that denoted the office concerned was complemented by the inclusion of a range of items, each of which contributed metaphorical references of their own.

An entirely contrasting question surrounding “material metaphor” arises from the interpretive practices of archaeologists themselves. Tilley usefully pointed out (1999, 82–101) how the metaphorical use of the term “megalith” in European prehistory served as a kind of short-hand that nonetheless entrapped the users into a self-sustaining, and also limiting, discourse. Archaeologists have deployed particular conceptual metaphors more self-consciously, however, to tie together a series of ideas about historical processes. Prominent among such theorizing was

a study by Ian Hodder in 1990 that dwelt upon the “Neolithic revolution” in western Asia and Europe, in which “domestication” was viewed as encapsulating as much a metaphorical relationship between humans and other species as an ecological or materially economic one. In that study it was the development of an opposition between the “domus” (as house and home) and the “agrios” (the world as perceived as being external to that of human society) that was seen as a prerequisite of the control over the reproduction of plants and animals that occurred in the relevant centuries. As such, it was proposed that the process of “becoming Neolithic” was one that involved the “domestication of society” itself.

The question inevitably arises from the breadth of studies involved, as to whether there can be a *general* theory of metaphor in archaeology and material culture studies. Tilley (1999, 260ff) certainly thought so, and argued that “solid” metaphors are not substitutes for linguistic metaphors or translations of them into material form (Tilley 1999, 263). Instead, the relationship between material metaphors and verbal/literary ones is interdependent or dialogical. So while verbal metaphoric expression often makes reference to, and carries most force using, imagery based in the material domain (“Peter was the rock upon which our Church was built,” for example), a material object may make metaphoric reference to a relationship normally articulated in words. Others, meanwhile, have seen certain material metaphors as having had a key role in the formation of emergent ontologies and as being in this way central to a “cognitive” reordering of social experience. Gary Webster (2001), for example, interpreted the form of late Nuragic period pots in Sardinia as representing a tension between an idealized represented “historical” set of social relations and those that actually obtained in a period of marked change.

Moreover, archaeologists have seen metaphorical structures as key means by which human cognitive development itself occurred in the past. Fiona Coward and Clive Gamble (2010), for example, have suggested that the corporeality of material culture and its potential as a source for both mnemonic and metaphor was drawn upon in periods even antecedent to the development of sophisticated linguistic expression. They cite the way in which the

production of flint/stone blades from cores produced a technology that vastly expanded the field of material expression; and how the disarticulation and re-articulation of animal bones facilitated the citation of human–animal relations from deepest prehistory.

Metaphor has in this and in other ways therefore become drawn into contemporary theories of materiality in archaeology, and in particular into conceptualization of the motivation and consequences for human engagements with things, and the relational nature of such engagement. One manifestation of this has been developed in reference to another early Neolithic site, Catal Huyuk in central Anatolia in modern-day Turkey. This has involved an exploration of the relevance of material metaphor to the concept of “entanglement” (Hodder 2012). According to this conceptualization, people not only habitually make links across domains both material and nonmaterial, but also become entrapped within their complexities. Metaphor plays a role in helping people find paths through the ideational maze that ensues, to bring “intellectual coherence” to their entanglements (Hodder 2012, 123).

The importance of metaphor, as Coward and Gamble have emphasized, is that people habitually think and act relationally, that is, in reference to the presence, actions, and motivations of those around them, and to the inherited and dynamic environments they inhabit. Metaphor facilitates contrast and comparison. It is a tool for thinking about the relationship of one phenomenon to another, one situation, condition, or state of being or behavior to another, and one person to another in terms of their practical and interactive “projects.” Material metaphors are durable and can serve as mnemonics of past states, past people, and what might be termed “absent presences.” Gavin Lucas (2012) has made an important point here in reference to archaeological residues and their intrinsically referential nature. The “archaeological record” is not a text, because it has rarely been composed deliberately in order to act communicatively, for the purposes of “reading;” many, perhaps most, residues reflect the unintended consequences and outcomes of action. Nonetheless, absent presences are routinely implicated in archaeological residues. The “equipment” concerned is also made up of practice and knowledge that people need to equip

themselves with in order to perform almost any action involving others. In this way, metaphor, as a practical resource with its rhetorical and cognitive attributes, but above all its relational and discursive power, stands at the core of social being rather than marking its periphery.

Material Symbols

ROBERT W. PREUCEL

Brown University, USA

Material symbols can be defined as symbols that have physical form. They consist of artifacts, art objects, buildings, monuments, landscapes, plants, animals, and even people. They thus possess an existence and durability that transcend the evanescence of the spoken word. Their physical character gives material symbols a permanence that can help establish and fix social meanings. As Hannah Arendt (1958, 137) put it, “the things of the world have the function of stabilizing human life and their objectivity lies in the fact that men, their ever-changing nature notwithstanding, can retrieve their identity by being related to the enduring sameness of objects.” Throughout this entry, I will use the term material symbols to refer to material culture, things, objects, and artifacts more or less interchangeably.

Because material symbols are a kind of sign, it is helpful to begin with a discussion of signs and how they carry meaning, the subject of the field of semiotics. Signs are generally defined as words or things that stand for something in the mind of someone. This “standing for” relationship is quite complicated and has been the subject of considerable research in philosophy, semiotics, linguistics, cognitive science, anthropology, and archaeology. Some scholars regard all signs to be arbitrary in the sense that the relationship between the sign and the thing being referred to is determined only by cultural convention. Other scholars regard some signs to be motivated in the sense of having a nonarbitrary relationship with their referents. All scholars agree that signs only obtain their meaning in context. Signs must be perceived as such by someone at a particular moment in time and different actors may regard the same sign differently. This variation is the basis for the claim that culture is a symbolic system

and highlights the fact that all interpretation is intersubjective.

Historically speaking, there are two main approaches to the study of signs. The first is the approach developed by Ferdinand de Saussure. Saussure conceived of semiology as a new science related to social psychology and devoted to the investigation of the general principles of signs. He regarded it as a unified field that was based upon language and including writing, sign language, Braille, symbolic rites, honorific speech, and military signals. Saussure recognized that his new science could be applied to all of culture, and famously asserted that by studying rites, customs, and so on as signs, it would be possible to create a semiological science complete with its own natural laws.

This insight was taken up and further developed by Lévi-Strauss and Barthes as part of their structuralist programs. Lévi-Strauss regarded linguistic phenomenon as a self-contained, structured whole and the appropriate model for the study of material culture. He applied his approach to the study of kinship, mythology, totemism, and history. Barthes advocated Saussure’s structural linguistics, but broke with Saussure on the generality of semiotics. He regarded it to be a subset of linguistics due to the primacy of discourse. He broadened out its subject to include literary texts, art, music, and fashion. These studies were widely influential and contributed to the emergence of semiotics as a major movement in literature and cultural studies in the 1970s and 1980s.

The second approach is that advocated by Charles Sanders Peirce. Peirce conceived of semiotics as an irreducible form of life encompassing man and nature and indeed the entire universe. Signs not only exist in the world, they also grow and continually produce other signs. All cognition then is a semiotic process that is mediated by signs. Peirce’s view of semiotics is inextricably linked to his view of pragmatism. To understand the meaning of a concept, one needs to examine its various contexts of use. However, this, by itself, is insufficient. Meaning can only properly be understood with reference

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

© 2018 John Wiley & Sons, Inc. Published 2018 by John Wiley & Sons, Inc.

DOI: 10.1002/9781119188230.saseas0367

to those logical concepts that establish a belief and that, in turn, facilitate the belief becoming a habit of thought. In use and experience, the sign's meaning grows.

Peirce defined the sign/referent relationship as being composed of three sign types: icons, indices, and symbols. *Icons* are signs that refer to an object on the basis of resemblance. They are "mimetic," an example being a diagram or a painting. An *index* is a sign that denotes its object by being affected or modified by that object. A weathervane, for example, points to the direction of the wind based upon the action of the wind on the tail of the weathervane. A *symbol* is a sign that obtains its character by virtue of some law, usually an association of general ideas. In this case, meaning is the result of convention. For example, a flag has no inherent meaning, yet it is commonly taken as a symbol of a nation. These three sign types have a hierarchical relationship such that symbols imply indices that themselves imply icons.

Archaeologists drew liberally from linguistic perspectives in the development of symbolic and structural archaeology. In a classic essay, Hodder (1982) reviewed the limitations of functionalism and structuralism, and highlighted the importance of the symbolic association of things. He argued that the meaning of an object resides not only in contrast to other objects, but also from its associations and uses in a network of references and implications. He further held that material symbolization is not a passive process and objects and activities "actively represent and act back on society" (Hodder 1982, 10). Reference is thus both dynamic and social.

Hodder (1990) demonstrated the value of this insight in an influential case study focusing on the European Neolithic. His main thesis was that symbolism must be addressed in order to understand adequately social and economic change. He proposed that in Europe and the Near East a particular set of concepts was central to the origins of agriculture and a settled mode of life. These concepts relate to the house and home—"domus"—and they provided a metaphor and a mechanism for social and economic transformation. As the wild was domesticated through ideas and practices surrounding the domus, people were brought in and incorporated into the social and economic life of the village. Over the

following millennia, cultural practices relating to the domus continued to change and develop, until finally they were replaced by a new set of concepts based on the warrior, the hunter, and the wild.

Shanks and Tilley (1987, 130) extended Hodder's symbolic approach in their consideration of material culture as an objectification of social being. They proposed that material culture does not directly reflect practices and structures, but rather mediates them through its own formal logic. Shanks and Tilley (1987, 131) identified three social fields in which material culture operates: technological, communicative, and ideological. Material culture can facilitate technological interventions as humans engage with the natural and social world. It can provide a communicative medium of symbolic significance. Finally, it can provide a medium for social domination as an expression of power and ideology. Significantly, they observed that material culture may operate in all three fields simultaneously.

Inspired by the post-structural critiques and discourse analysis, Tilley (1999) introduced the idea that material culture can be understood as a "solid metaphor." He noted that solid metaphors are not substitutes for linguistic metaphors, nor are they translations of them into material form (Tilley 1999, 263). Rather, they condense meanings in a manner that might require a number of linguistic metaphors to accomplish a similar effect. Material metaphors typically signify in nonarbitrary ways linked to their specific qualities, such as shape, structure, color, texture, and form. Tilley identified the human body as a rich source of metaphors for organizing and understanding the social world. As he puts it, the human body is "metaphorically intertwined with the social body and itself patterned and constructed through this integration" (Tilley 1999, 37). He observed that if the body is society, then parts of the body may represent different parts of society. He drew attention to the common right and left dualisms where oppositions are set up between sacred and profane, birth and death, light and dark, and so on. He noted that spatial oppositions such as inside and outside, near and far, center and periphery are based upon the body.

Tilley applied his approach to the study of southern Scandinavian rock art dating to the end of the Bronze Age. In a detailed analysis

of Högsby, Sweden, he concluded that there is a structural order to the rock art in a south to north sequence. He interpreted the rock art as providing a focus for processions and ritual ceremonies associated with becoming human. He regarded the rock art narrative at Högsby as linked to the regeneration of life, the passage of the seasons, and the relations between land and water. He regarded specific images as having multiple meanings, “multidimensional chains with shifting and transformational relationships between signifiers whose meaning becomes contextually transformed according to their location in the series of carved rocks and their relationships to other signifiers on individual carving surfaces” (Tilley 1999, 173).

The language model has proven to be of limited value for material culture. Hodder (1982) observed that, unlike spoken language, material culture meanings function in nondiscursive and implicit ways. Moreover, material symbols are not arbitrary, as are words, since the content of the sign affects the structure of its use. Shanks and Tilley have also critiqued the linguistic model. For them, material culture is a coded sign system that constitutes “its own material language” in the context of production and consumption (Shanks and Tilley 1987, 101). It does not simply reflect the signification structures of language in another form. Rather, it is “constituted in terms of a spiraling matrix of associative and syntagmatic relations involving parallelism, opposition, linearity, equivalence and inversion between its elements” (Shanks and Tilley 1987, 103). Material culture is thus implicated in a material discourse that is bound up with social practices involving power, sectarian interests, and ideology.

Some archaeologists have turned to the semiotics of Peirce as a means of addressing the limitations of a Saussurian model. Preucel (2006) has reviewed the advantages of a Peircian perspective. For example, Saussure’s dyadic sign theory brackets off things-in-the-world because of its emphasis on the language system. Peirce, in contrast, has a place for things in his tripartite sign formulation. Saussure emphasizes unmotivated relations and regards the signified–signifier relation as arbitrary. It implies only the oppositional relation of difference. Peirce recognizes arbitrary relations with his symbols, but he also identifies two kinds of motivated relations, namely icons

and indices. Saussure focuses on the structure of representation. Peirce focuses on the pragmatics of mediation and how signs generate new signs through situated social practices.

Some scholars have investigated how different kinds of signs were bundled in strategic social practices. Preucel (2006) investigated the linguistic and material elements of indigenous discourse during the period following the Pueblo Revolt of 1680. Historical documents reveal speech acts by Pueblo Indian leaders seeking to persuade their followers to relinquish Spanish customs and practices and return to a lifeway consistent with the laws of their ancestors. Preucel then examined settlement location, architectural form, and pottery design and found archaizing elements. He concluded that these material symbols functioned alongside linguistic discourse as mutually supporting practices and that they collectively mediated a new form of temporality and created a new social being.

Joyce (2007) examines the recursive, experiential aspects of figurine use in northern Honduras between 1,100 and 200 BCE. She notes that her study is, properly speaking, a study of meaning-making rather than meaning *per se*. She observes that the figurines themselves point toward the existence of active social agents making marks that we recognize as meaningful. She finds that different hair treatment functions as a special locus of iconic significance, and finds that hair-styles appear to vary with the age of the represented person. She then notes that the symbolic meaning of these figurines remains elusive because of the difficulties associated with understanding conventions associated with their community of production and use. Her analysis thus reveals the limits of interpretation, and multiple ways in which signs can be understood by both contemporary scholars and past actors.

There is a growing interest in studies of networks and entanglements. Knappett (2011) has drawn attention to the importance of network thinking combined with the advantages of shifting focus from material culture to materiality and from objects to assemblages. Inspired by Bruno Latour’s actor network theory, he emphasizes the need to decenter human agency and consider an “enactive” approach where humans and nonhumans bring each other into existence. Each enables the other, thereby locating agency

jointly in them. In a similar fashion, Hodder (2012) argues that people and things have a long evolutionary history. Their entanglement can be seen as emerging from the dialectic of dependence (reliance) and dependency (constraint and limitation). Entanglement is both a condition of being in the world and a process of entities linking together in networks or assemblages. Significantly, entanglements have temporalities that things impose on humans due to their natural lives and this gives entanglements a direction.

Another important research trajectory has been the origins of symbolism and modern behavior. This topic is usually linked to language and tool use. Some scholars hold that symbolism developed in Africa, in conjunction with the gradual biological evolution of our species. Modern behavior is linked to the emergence of modern language on the assumption that enhanced communication ability would have had clear evolutionary advantages. Yet other scholars believe that symbolism and cultural modernity may have developed independently or been acquired at different times, by a range of hominids, including Neandertals. Most scholars agree that a fundamental turning point in human evolution was when humans were first able to use material symbols to locate memory outside the body. The abstract patterns engraved on pieces of ochre found at Blombos Cave in South Africa and dating to 100,000 years ago appear to be among the earliest manifestations of this ability. Donald (1991) proposes that “external symbolic storage” constitutes a major factor in human conceptual development. Similarly, Mithen (1996) argues that the conscious use of material culture to store information is a fundamental feature of any specialized (domain-specific) intelligence. This is a dynamic subfield and it is likely that additional refinements and new theories will emerge with additional discoveries.

Cognitive archaeology has emerged as a subfield focusing on the cognitive processes related to the changing conditions in the material domains of life. Significantly, Renfrew defines the field as the study of the special human ability to construct and use symbols. His “material engagement theory” advocates shifting attention away from objects to the fluid and relational transactions or relations between people and things (Renfrew

2004). Malafouris (2013) has further developed Renfrew’s approach. He provides empirical and historical evidence for the ways in which material artifacts are not merely aids to an internal cognitive process, but are in fact integral to the process itself. He also introduces the idea of enactive signification. Enactive signification refers to the mode of signification wherein the meaning of a sign is not symbolically encoded in the sign as a representation, but rather is located in the interactive process itself. For example, he suggests that numeracy was not merely encoded onto clay material as though it were a recording of a mental process, but rather, the clay itself acts as a means of providing signification by enabling a qualitatively different cognitive process.

Finally, it should be noted that several new studies, influenced by the “new materialisms,” emphasize the vital force of material culture in the world. The basic claim is that material culture needs to be radically reappraised and people and things need to be considered as ontologically equivalent. Archaeologists differ on the nature of this reappraisal. For some, this involves a shift from material symbols to vibrant materials. Jones and Alberti (2013, 23) argue that it is critically important to examine how materials and persons are assembled. For others, it involves the consideration of object agency independent of humans. This view underpins symmetrical archaeology (Olsen 2010) and various post-humanist approaches. These critiques are valuable in drawing attention to the boundaries of the materiality concept. However, they risk relegating real-world, social issues to secondary significance.

Material symbols are the primary physical expression of human sociality. They constitute the social resources for communication and the mediation of social practices. There continues to be considerable debate among archaeologists regarding how best to model material symbols in the communicative process. Do they function like language, or do they occupy their own separate domain? What does the decentering human agency mean for understanding material culture and the evolution of symbolic behavior? However these questions are resolved, it must be acknowledged that material culture and language are deeply imbricated, as a sociosemiotic

approach would argue. Linguistic acts typically accompany the use of things in context. Their fates are necessarily intertwined.

Memory and Remembrance

RICK PETERSON

University of Central Lancashire, UK

Memory has been an intensively studied and theorized area within archaeology since the beginning of this century. Out of this debate has come a variety of perspectives, drawing on a wide range of research in the natural and social sciences. These have, in turn, led to a range of different definitions of what we mean when we talk about memory and how we might usefully research memory in archaeology.

It is helpful to begin by offering some definitions. The archaeological study of memory has been concerned with the material manifestations of memory and remembrance. Theory around memory and remembrance in archaeology has also been predominantly concerned with the operation and creation of memories at a group or social level. Additionally, recent theory around memory has drawn on a wider concern within the social sciences on embodied (see EMBODIMENT) and experiential understandings of the self. These can be contrasted with another, equally valid, set of archaeological questions around memory.

How do the results of current archaeological research contribute to the construction of memory (see MEMORY) in the present? In this entry, the aim is to discuss embodied theories of practice around memory. How did people in the past remember with material culture?

Classical philosophy on memory, from Plato's dialogues up to John Locke's concern with the "self," can be characterized as being concerned with an inward-looking analysis of personal and individual memory. By contrast, phenomenological approaches to memory in the work of Edmund Husserl and Maurice Halbwachs made an explicit link between the creation of memory and the experience of living within a group of people. Borić (2010) provides a detailed exegesis of this distinction from an archaeological

perspective, based on the work of Paul Ricoeur. This communalization of memory has been an important influence in the way that social theory has discussed memory as an explicitly social phenomenon, a property of the group rather than of the individual.

From both phenomenological traditions of philosophy and studies in cognitive science we can discern the importance of habitual, physical encounters in creating memory. Andrew Jones (2007) draws on Andy Clark's work in cognitive science to describe the interaction between the brain, the human body, and the world as one of overlapping "fields of interaction." The mind and, by extension, memory is created in the embodied interaction between the material world, the body, and the brain. This kind of habitual memory is often unconscious and it can be regarded as the foundation for people's integration in their particular society—their habitus in Pierre Bourdieu's terms.

Therefore, in contrast to "classical" philosophical and psychological examinations of memory, which treat memory as an internal property of individual identity, modern social theory has discussed memory, by definition, as a social phenomenon. The subset of this social theory which is concerned with embodied and material perspectives on memory is, for obvious reasons, the most relevant for archaeological enquiries into memory and remembrance. The foundations of the embodied social approach to memory were laid in Connerton's (1989) book *How Societies Remember*. In this work, Connerton treated memory as a cultural phenomenon and attempted to explore the ways in which group memories were transmitted in nonwritten ways. He showed the importance of ritual performances to inscribe social memory on the bodies of the participants. Connerton's work is also important for the connections it draws between the semi-unconscious habitual memory discussed above and other kinds of memory. For Connerton, habit-memory is one of three broad classes of memory claim, the other two of which are personal and cognitive memory claims. Personal memories "take as their object one's life

DOI: 10.1002/9781119188230.saseas0371

history.” Cognitive memory claims are memories of abstract knowledge, while habit-memory is the memory of how to perform an action physically. These last two kinds of memory claim share the characteristic that you do not need to remember when you learnt something to make use of it (Connerton 1989, 22).

At this point it is necessary to consider in rather more detail the way in which the passage of time is experienced by people to create different kinds of memory. In *The Perception of the Environment*, Tim Ingold (2000) develops both a “dwelling perspective” and the concept of “temporality” to address precisely this issue: For Ingold, agency is developed through the experience of time and of memory.

People dwell within environments made by previous human activity. Everything they do is structured by those pre-existing environments and in turn their actions create new kinds of environment. Ingold develops this theme of temporality by coining the neologism “taskscape.” The “taskscape” can be thought of as an array of temporally related activities which is analogous to “landscape” as an array of spatially related features. Ingold (2000, 199) uses the phrase temporality (see TIME AND TEMPORALITY) to describe a conception of time, based on the phenomenological philosophy of Maurice Merleau-Ponty, and which is therefore not dependent on particular models of human consciousness and which does not need to be calibrated to a scientific measurement of time. For Ingold, people make time pass when they do things: Temporality is the time of the participant.

One useful contribution to thinking around the role of material culture in the transmission of memory is provided by the concept of the “index” used by Alfred Gell (1998) in *Art and Agency*. For Gell, the artist and the artwork are inseparably linked in time; in Ingold’s terms, the artwork is part of the taskscape of the artist. In addition, all artworks reference earlier works. They would not be comprehensible as art without this connection and through this link they connect the artist and the viewer to those earlier artworks. As they are making the artwork the artist is physically incorporating their bodily actions into the object. Gell (1998, 236–237) does not claim that objects themselves experience memory, or even that they work as an external store for human memories.

Instead he borrows the term “abduction” from semiotics to describe the way they permit people to make “causal inferences” about things that happened in the past. From the embodied perspective described above, we can see physical changes to artifacts and landscapes as evidence for the creation of memory in the past. This can potentially provide archaeologists with a methodology to investigate memory claims of all three types identified by Connerton.

Andrew Jones (2007) has analyzed the role of material culture in memory by drawing on the actor network theory (see ACTION THEORY) of Bruno Latour and colleagues. His focus is on the act of remembering, which he would see as both an embodied and social process; people require both other people and things in order to remember. Jones takes from Latour the insight that we do not need to give priority to either brains, bodies, or artifacts in this process. He refers instead to the act of remembering arising from the relationships between a “company of actors.” Therefore, for Jones, it makes little sense to make distinctions between internally or externally stored memories, or even between social and individual memories. Rather we need to think about material culture (see MATERIAL CULTURE) (broadly defined) and the way it acts to permit the practice of remembering. Objects can act as metaphors which crystalize and index short-term events. Monuments can index events which have taken place. However, they also have the properties of permitting or blocking certain kinds of physical activity. This is particularly important when it comes to the role of large-scale commemorative ceremonies, social remembering practices which are aimed at creating a particular kind of memory.

In his review of the role of memory studies in archaeology, Dušan Borić (2010) follows Jones in arguing that distinctions between different kinds of memory claim, while analytically useful within philosophy, are less helpful in archaeology. He proposes that archaeological analysis is better served by a temporal focus on the processes of memory, for which he draws on Ingold’s (2000) dwelling perspective. The first of these is the trace, the physical imprint of past actions. Borić points to the problematic status of the “trace” as something that has been treated as both a conceptual tool and a metaphor. However, for the purposes of this argument, “trace” can be thought

of as the embodied, materialized evidence of past actions, directly equivalent to Gell's (1998) "index." For Borić, "trace" leads to "citation." When people respond to traces they do so within a new temporal framework. So, rather than inferring past agency from indices, in the way suggested by Gell, Borić argues that people "cite" these traces in a new contemporary set of relationships. Remembering is a process that takes place in the present, drawing on the presently available "company of actors." However, the same traces and citations can be drawn upon in more than one present, which leads Borić to the third of his analytical categories, "recapitulation." By repeating practices in the same places, traces can be cited in ways that are both traditional and innovative. Therefore, material culture and landscape can be deployed to create and modify memories as well as to "preserve" them.

The importance of bodily performance is clear in all these accounts of the practice of remembrance. Formal bodily performance was also an important part of Connerton's analysis of the creation and managing of collective social memory, in his case focused on the large-scale rituals of organized religion and nation-states. Peterson (2013) has reviewed the specific importance of embodied performance at all scales of analysis. Following Jones in focusing on practices of remembering, it can be argued that even small-scale habit-memories require an embodied performance. Bodily skills, for example learning to work stone, are learnt from a combination of feedback from the material being worked with approbation from an experienced audience. What is being created in this case are indexing traces on the landscape, the artifact, and the body, all of which will be drawn on in future citations. As well as the stone tool and the production site, the lithic worker has created the kind of body that knows how to work stone. The citation and repetition involved in these performances is another instance of the continuity of practices of remembering across the scales from personal habit memory to large-scale commemorative performance.

Therefore, building on the literature discussed above, the archaeological study of memory and remembrance is characterized by the analysis of a number of important topics. These include: the relationships between people, landscape, and

material culture; evidence for embodied performances; transformations to bodies, objects, and places which act as indices or traces; and the ways in which these changes are cited and recapitulated in subsequent times.

A specific example of these processes being used to deliberately create lasting memories can be seen in Howard Williams' (2001) application of the archaeology of memory to the study of early medieval funerary rites at Sutton Hoo in Suffolk, UK. This site is a royal barrow cemetery dating to the sixth and seventh centuries CE which, alongside the famous ship burial, contains other high-status inhumation and cremation burials beneath 19 large barrows. The site itself is on a prominent location above the Debden estuary, which is likely to have lain on the contemporary route to the East Anglian royal site at Rendlesham. Williams argues that funerary performances at Sutton Hoo would have replicated the route from the sea to the cemetery taken by the ship in mound 1 before burial. Funerary processions therefore would be both citing earlier processions and making the dead visible by creating traces or indices to commemorate them in the landscape.

The most obvious of these traces would be the barrows that cover the graves. Williams analyzes the way that these barrows are structured by the indices of earlier activity and how they recapitulate and cite each other. He argues that the large complex barrows, which contain complex assemblages of material culture and evidence for animal sacrifice, are the physical traces of large funerals. They are widely spaced, which Williams argues is the result of each barrow being carefully sited in relation to existing monuments. This is interpreted as a way of deliberately creating physical indices of the dynastic connections between the different occupants of the barrows. Although there are no prehistoric barrows at Sutton Hoo, Williams cites other early medieval burials which cluster around pre-existing Bronze Age monuments, to suggest that the overall form of the pagan Saxon barrow is itself a citation of the deep past.

Williams analyzes the transformations around the inhumation burial in mound 17 to show how the ritual performance both cites earlier funerals and allows the incorporation of unique elements for that particular individual. Funerary

performance would have focused around the deep oval pit at what would become the center of the mound. A complex assemblage of grave goods was used to create a particular identity for the dead. The first artifacts placed in the pit were spears and above them was a group of cauldrons, a bucket, shield, bowl, bag, and horse harness fittings. Once these items were in the grave the coffin, containing the body of an adult male accompanied by a sword and a purse, was lowered on top of them. A comb was placed on top of the coffin before attention shifted away from the main grave. A horse was sacrificed and buried in a second pit around 1 m away. After this event the main mound was constructed to cover both pits. Thus, the mound 17 funeral would have involved a complex set of performances around the structured display and concealment of the body and artifacts, with the process being indexed by the construction of the mound.

The preceding discussion has concentrated on the “positive” aspects of memory. However, memory can also be a problematic experience. Borić (2010) has noted the personal and social costs of remembering traumatic events. In particular, he has noted the difficulties in dealing with the excess of historical memory in the countries of the former Yugoslavia. Jones (2007) also considers this point; drawing on the work of Michael Stewart, he points out how strategies for dealing with traumatic social memories can vary dramatically from group to group. Both the Jews and the Roma experienced the Holocaust. In contrast to the well-documented commemorative practices around Holocaust memory in Jewish culture, the Roma do not explicitly “commemorate” the events. Rather, Stewart argues, Roma groups externalize these difficult memories by situating them in their interactions with wider society. Therefore, these memories are physically indexed by a whole suite of material culture associated with the boundaries between Roma and non-Roma society.

Memories can also be deliberately suppressed, at both a personal and group level. There are good archaeological examples of this process, particularly around the role of iconoclasm in the deliberate erasure of memory. The Roman tetrapylon, or four-way triumphal arch, which stood at the center of the legionary fortress in Caerleon, Monmouthshire, UK, survived, along

with the fortress bath-house, as an intact structure into the medieval period. Ray Howell (2000) has shown that by the early thirteenth century these monuments had become directly associated with the growing literature around King Arthur. He argues that the simultaneous demolition of both of these structures was a deliberate act of iconoclasm arising from the disputes between Welsh and English lordships over the control of Caerleon. Pamela Graves (2008) provides a detailed archaeological analysis of the process of iconoclasm in sixteenth- and seventeenth-century England. This allows us to see deliberate practices of (enforced) forgetting, which closely parallel the practices of remembering we discussed earlier. Graves demonstrates how iconoclasts in early modern England had an embodied and material understanding of how certain “indices” in religious artworks acted within memory practices around traditional Catholic worship. The heads and hands of religious images were the most important trace or index in this process and, therefore, they were purposefully targeted by the iconoclasts. These fragmented images were then deliberately left on display. The images then functioned as a, literally, reformed index. Anyone encountering these images would then have been able to draw on both the original traces, their citation and rewriting by the iconoclasts, and the recapitulation of the original acts of devotion as an act of destruction. The reformed images would have been central to the new understandings of the past and the changing religious orthodoxy promoted by the iconoclasts.

An embodied and material approach to archaeologies of memory and remembrance can therefore be seen to be applicable at both a group and personal level, to cover both practices of remembering and of forgetting, and all of the postulated “levels” of memory from unconscious habit-memory to the most complex and discursive accounts of the past.

Mind and Cognition

ANTONIS ILIOPOULOS

University of Oxford, UK

Mind and *cognition* are two terms interchangeably used by archaeologists trying to approximate past ways of thinking. Cognitive archaeology, or the archaeology of mind (as it is also called), is a sub-discipline that moves past post-processualism's preoccupation with *what* past peoples thought, by focusing on *how* they carried out their cognitive processes. While early such attempts can be traced back to the 1970s, "cognitive-processual" archaeology grew in the 1980s, becoming officially established at a conference organized by Colin Renfrew and Ezra Zubrow in April 1990 at Cambridge, UK. Since then, cognitive archaeologists and affiliated scholars have been able to account for multiple facets of prehistoric and historic minds, ranging from technological to ideological, linguistic, and artistic.

A major focus of discussion, since the 1980s, has been the evolution of the "modern" human mind. In order to illuminate the origins of cognitive modernity, scholars have set out to detect modern human behavior from archaeological proxies, such as composite tools, complex hearths, organized domestic space, long-distance exchange networks, fishing, mobility strategies, burials, cave art, figurines, and ornaments. While such evidence had been associated with the European Upper Paleolithic up until the turn of the millennium, the recent discovery of bone tools, engraved ochre pieces, and shell beads has pushed the appearance of behavioral and cognitive "modernity" back to the African Middle Paleolithic/Middle Stone Age.

These artifacts have already been used to make inferences about a range of cognitive processes. The technological capacities required for manufacturing and using tools were among the first to be studied, given their position at the starting point of the archaeological record, as well as the fact that they exhibit increasing

complexity over time. Most notably though, the archaeology of mind has been preoccupied with the capacity for symbolism. Imbuing the material world with arbitrary and conventional meaning is generally considered as a defining feature of the human condition because the storage of information outside the brain allowed humans to communicate their cultural values to others. As would be expected, this cognitive Rubicon has been closely linked with the appearance of modern language—another ability that has taken center stage in cognitive archaeology. Yet, besides symbolism and language, cognitive archaeologists have also studied various other capacities such as working memory, joint attention, visuospatial and abstract reasoning, long-term planning, self-awareness, theory of mind (i.e., the understanding of false beliefs and other abstract mental states, such as higher-order desires), and level-2 perspective-taking (i.e., the ability to inhibit one's own perspective and comprehend how an object looks from another person's perspective).

Being able to infer cognitive processes from the material record is without a doubt an ambitious endeavor. Cognitive archaeologists have long recognized that the meanings of past practices cannot be deciphered because "cognized" categories held by past minds cannot be directly accessed. This does not, however, render the material evidence incapable of shedding any light on the thought processes carried out by past peoples. On the contrary, the artifacts discovered by field archaeologists can prove particularly telling when examined under the prism of theories drawn from the philosophy of mind and cognitive science. Yet, the most suitable method to examine material culture has been at the center of much debate, especially since the turn of the millennium, when a new school of thought challenged the traditional take on cognition. Dissonance mainly stems from the contradictory ways in which scholars have been approaching two main issues: (1) How did past minds function? and (2) How did they come to be? As shall become clear in the following sections, the ways

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

DOI: 10.1002/9781119188230.saseas0383

in which archaeologists have been studying the nature and evolution of cognition has proven an interdisciplinary affair of diverse forms.

The nature of cognition

Those invested in the origins of the human mind tend to automatically equate it with the prodigious brains of a selected few (e.g., Mithen 1996; Klein 2009; Henshilwood and Dubreuil 2011; Hoffeecker 2011). This sort of methodological individualism, which locates cognition inside the head, is inherently engrained in the Cartesian and computationalist way of thinking that has long dominated the sciences. It is generally taken for granted that a brainbound apparatus collects input from the world, in order to construct symbolic representations that are, in turn, used in the computations underlying cognitive tasks. These mental operations produce internal templates that are subsequently materialized into the external world by way of deliberate behavior. Seen through the prism of representational nativism, Middle Stone Age shell beads such as those discovered at Blombos Cave are generally treated as the epiphenomenal products of symbolically capable brains, that intentionally imbued them with symbolic meaning, in order to communicate personal and social information to others (Kuhn and Stiner 2007). Associating material culture with the representation of predefined notions, cognitive archaeology has been—from the outset—largely preoccupied with a representational mechanism linking mind and matter.

This representationist take on the relationship between mind and matter cannot, however, explain how the brain can know aspects of the world prior to their empirical instantiation. In addressing this issue, Renfrew (2001) proposed that concepts arose in unison to their physical manifestations, as is, for instance, the case with the concepts of “weight” and “value.” Given that these kinds of meaning depend on more than the individual, he placed the foundations for a paradigm shift that treats cognitive systems through an anti-representationalist lens. From an empirical point of view, concepts are actually grounded on concrete experience; and since much of everyday thinking takes place through

our skilled engagement with the physical world, it would be mistaken to reduce the “cognitive” to the “symbolic.”

In light of the “internalist” dictum’s shortcomings, an “externalist” wave of cognitive archaeology has come to extend the boundaries of cognition beyond the confines of the braincase (e.g., Knappett 2005; Malafouris 2013). In fact, according to a theoretical framework known as Material Engagement Theory (MET), it may be better to speak of the mind as having no location whatsoever (Malafouris 2013, 85). For its proponents, cognition is actually brought forth through an intricate dialectic process between brains, bodies, and things. Rather than granting the brain with ontological priority, MET has been making a case for the priority of material engagement. Against the view that sees material culture as a premeditated invention, the theory of material engagement attributes its creation to a process of enactive discovery. Adhering to a novel theory of cognition known as enactivism, this theoretical framework posits that, instead of representing the world, humans amass knowledge by using artifacts to probe their environments. Given that these objects do not just incite, but actively shape the very forms of human thinking, scholars subscribing to an enactive sensorimotor account consider the material world a constitutive part of cognition. From the vantage point of MET, artifacts, such as the aforementioned beads, are not the epiphenomenal products of symbolic templates, but the material scaffolds required for the realization of significative and especially, symbolic ornamentation (Iliopoulos 2016). As we shall see in the following section, reconceptualizing the relation between mind and matter is closely linked to a reconceptualization of cognitive evolution.

The evolution of cognition

The evolution of the human mind has been mainly studied from a Neo-Darwinian perspective, which attributes our unique cognitive abilities to neural advances of adaptive relevance (e.g., Mithen 1996; Klein 2009; Henshilwood and Dubreuil 2011; Hoffeecker 2011). According to the archaeological consensus, looming ecological

problems, such as changing environmental and demographic demands, are responsible for exerting the selection pressures that drove the development of adaptive behavior and cognition. This assumption leaves room to neurocentrism, according to which artifact-related concepts are first processed by homuncular systems at the subpersonal level, and are then transferred into awareness at the personal one. Only once bestowed with an evolved mental architecture were modern humans able to deliberately produce an array of cultural practices for the purpose of addressing the impending need to transmit cultural information to a greater number of people. The rate of transformation from archaic to modern human beings has been widely debated, with some scholars arguing that modernity was the result of a sudden break with earlier behavior, others favoring a more gradual and mosaic development, and still others arguing that innovations are not restricted to our species and appear and disappear in Africa, Europe, and the Near East between 200,000 and 40,000 years ago before becoming fully consolidated. Despite their differences, most scholars seem to agree on attributing cultural innovation to prior biological evolution, essentially making a clear distinction between the two trajectories. As they see it, the former is the epiphenomenal product of the latter because function is purportedly preceded by structure. From this neo-evolutionary point of view, the appearance of artifacts such as the Blombos beads has been attributed to prior structural reorganization and expansion of particular cortical areas (Henshilwood and Dubreuil 2011).

This tendency towards biological reductionism has been recently critiqued on the count that the interaction between biological and cultural entities is much more fundamental than commonly assumed. According to recent developmental perspectives (e.g., developmental systems theory, probabilistic epigenesis, and neuroconstructivism), biological and cultural evolution are intimately entwined dimensions of the same ontogenetic process. For the proponents of these post-genomic metatheoretical models, social practices are not the transcribed products of genetic or cultural codes—they are instead the dynamic catalysts and products of complex

developmental processes that involve bidirectional influences within and between genetic, neural, behavioral, and environmental levels of analysis. In this light, social scientists have started replacing the linear and genetically deterministic stance towards evolution with an ontogenetic or developmental approach.

From the long-term societal perspective of archaeology, the theory of material engagement has focused on tracing the diachronic ontogenesis of the human mind (Malafouris 2013). Drawing from developmental neuroscience, its proponents posit that the neural substrates of cognition are amenable to continuous change. Given the remarkable plasticity of the human brain, MET refutes the prevalent notion that it has remained the same since speciation. In fact, not only has this organ changed much over the past 200,000 years, but also its constitutive entwinement with material culture has shown great diversity. According to Malafouris (2013, 46), the embedment and inextricable enfoldment of our plastic mind in a plastic culture may well be the defining trait of our species. Doing away with the notion of *modernity*, MET urges cognitive archaeologists to explore this system-wide *metaplasticity* by tracing the ongoing evolution of historically situated ways of thinking. To return to our case example, the significative concepts associated with the aforementioned beads were not envisaged by already evolved brains; they were instead brought forth through long-term processes of material engagement (Iliopoulos 2016).

Future directions in research, theory, and methodology

In moving away from the relativist agenda of post-processualism, cognitive-processualist archaeologists set out to develop a rational methodology that would allow them to use artifacts in order to infer properties of past minds. Yet, despite aiming towards a universal method, the field evidently took quite distinct forms. Until recently, it was the Cartesian and neo-Darwinian dictum that drew the lion's share of attention. In fact, such was the automatic predisposition of scholars towards a dualistic and deterministic outlook that it was often assumed without

explicitly considering its theoretical implications. It should come as no surprise though that carrying through with the bold task of accounting for entities as elusive as past minds requires an empirically supported and analytically precise epistemology. This framework should be able to use the archaeological record in order to infer behavioral systems, which it can in turn link to mental and eventually neural systems (Garofoli and Haidle 2014).

To connect artifacts with behaviors, minds, and brains, archaeologists must draw upon the theoretical and experimental findings of other areas. As we have seen, transgressing the boundaries of archaeology has already provided us with the analytical tools required for studying the biological, social, and cultural foundations of the human mind. Delving further into the study of past minds can veer towards many fruitful directions. For one, the thought-and-action processes required for the manufacture and use of tools can be identified by coding the physical actions involved in their construction into sequences of operational units depicted in “cognigrams” (Haidle 2012). Studying the origins of material signs, on the other hand, would necessitate a semiotic analysis of behavioral systems. By employing a rigorous theory of semiotics, cognitive archaeologists will not just be able to describe the perceptual and conceptual interpretations of past peoples; they will also be able to account for the evolution of material signification from physically founded to entirely arbitrary meanings (Iliopoulos 2016). The semiotic capacities gleaned from archaeologically visible behaviors can in turn be mapped onto neurocognitive systems. The neural architecture required for supporting different kinds of thinking can be explored by integrating the theoretical and experimental findings of neuroscience into archaeology (Renfrew et al. 2008). This collaborative platform, known as neuroarchaeology, has already employed neuroimaging methods in order to address the development of practices that are especially pertinent to archaeology. A materially sensitive neuroarchaeology thus appears to be a promising route towards understanding how various artifacts incited and shaped the thoughts carried out by past peoples, as well as for tracing how the synergistic fusion of their brains, bodies, and things changed while they

were traversing through distinct spatiotemporal trajectories.

New Materialisms

RACHEL J. CRELLIN

University of Leicester, UK

New materialisms is the term used to describe a variety of theoretical approaches that share a commitment to the importance of “the material” in our world. New materialisms differ from traditional materialist, and particularly Marxist, approaches in their commitment to an alternative understanding of the nature of matter. The approach is relational (see *ASSEMBLAGE* and *SYMMETRICAL ARCHAEOLOGY*), emphasizing the ways in which materials, people, things, animals, plants, and places are the product of their relations and their properties, and potentials are defined by these relations. The understanding of matter adopted by new materialists has a range of consequences for agency, the position of humans within our ontologies, the role of dualisms, and how we understand history, change, and cause and effect.

In traditional approaches, matter is viewed as an inert substance—the brute, dead, solid foundation of the world around us. This position, drawing on Descartes and Newtonian physics, suggests that the solid world of matter is quantifiable, bounded, and static. Matter does not move or change without the application of another force; it is predictable and controllable. Coole and Frost (2010, 8) term this the Cartesian–Newtonian understanding of matter. In contrast, new materialists adopt a stance, drawing on both philosophy and the increasingly complex views of what matter is, and is not, which are emerging from the natural sciences, to argue that matter is lively and ever-shifting, capable of change without the need for outside forces, unpredictable and uncontrollable. Matter is not static and nor is it clearly bounded in new materialist approaches.

The traditional view of matter has led to a position where humans are seen as exceptional. Matter is portrayed as passive, predictable, and controllable, whereas humans in contrast are active, rational, unpredictable beings with their

own agency (see discussion in Coole and Frost 2010, 7–8). It is humans who have the ability to change the material world around them and impose their will on a blank canvas of materials. It is also humans, who, through our ability to measure and describe matter, are able to understand the world around us. If, however, we adopt the new materialist stance on matter, that it too is lively and unpredictable, then the position regarding agency also shifts. Bennett (2010), for example, takes a vitalist position and advocates that we recognize what she terms “thing-power.” For Bennett, materials are *vibrant*, by which she means always changing and in flux; they are equally capable of acting in the world. Bennett’s concept of vibrant matter gives us a sense of change that is not only the result of what is traditionally termed human agency, but instead comes from materials themselves which she views as never static, stable, or complete. Bennett and other new materialists are not just granting what is often termed, following Alfred Gell, “secondary agency” to materials; rather they are recasting agency completely. In Bennett’s work we see the role of trans-fats in the obesity crisis and a wildfire and company policy in an electricity blackout. Human agency, for Bennett (2010, Chapters 1 and 2) is just another case of thing-power.

Rethinking what, and who, might be capable of being seen as active in our world has clear consequences for ontology. New materialisms may be characterized as nonanthropocentric or even post-human, and proponents often state that they work from a “flat ontology.” In the Cartesian–Newtonian model of matter, humans occupy the ontological apex. It is humans who can measure and know the world, and thereby humans, and their attendant culture, have come to dominate and master the world of nature: Humans are the most important players in the world. Post-human and nonanthropocentric approaches argue that humans are only “one of many” who shape the world. Those who start their research from a “flat ontology” are happy for plants, animals, things, materials, and landscapes, as well as humans, to all emerge as agentive and

DOI: 10.1002/9781119188230.saseas0409

potentially important in the narratives that they write. This does not deny or exclude a role for humans, but rather asks that we also give the rest of the material world its due. It also does not ask that we understand humans, animals, plants, things, and materials as the same; indeed, new materialists, drawing on the work of Gilles Deleuze, often revel in difference. Adopting a nonanthropocentric approach has clear consequences for blame and ethics and as a result it is viewed as radical and controversial by many.

The ontological position adopted, and the view that all matter is active and capable of change, results in a position that rejects dualisms, dichotomies, and oppositional thinking. By arguing that all matter is active, new materialists often reject a separation between the animate and inanimate. For many it also results in a rejection of divides between the organic and inorganic, sentient and nonsentient. DeLanda's work highlighting the flux inherent in geological strata illustrates the way in which it is not that matter is dead and inanimate; it is rather that we are not capable of perceiving the scale of this animacy. By disregarding the divide between the animate and inanimate and also adopting a nonanthropocentric approach, new materialists tend to avoid oppositional thinking entirely. In archaeological theory the questioning and rejection of dualisms and dichotomies reaches back to the influences of phenomenology on the discipline. For prehistoric archaeologists in particular, a reliance on Cartesian dualisms to explain the history of pre-Descartes periods has been heavily critiqued. The new materialist rejection of Cartesian dualisms is perhaps one of the reasons that the approach has come to appeal to many archaeological theorists; conversely, the rejection of the animate-inanimate divide can be seen as controversial and problematic by other archaeologists.

Adopting a new materialist approach has consequences for causation and, as a result, for how we approach history and change. For new materialists, cause and effect are not simply and unproblematically linked. Rather, the relational nature of the world and the animacy of matter means that causation is always complex and multiple. This is perhaps best explained by recourse to the concept of assemblage adopted by many new materialist thinkers. In assemblage theory the

world is understood to be made up of diverse, heterogeneous components such as things, people, animals, plants, and landscapes, all of which exist enmeshed within varied and multiple relations. Assemblages refer to the groups these components might find themselves in. Assemblages are always temporary and never fixed in either time or space—they exist at every scale, from the atom to the institution. Given that assemblages are complex, relational, interlocking wholes, simplistic, singular models of causation cannot be sustained (see, for example, Bennett 2010). As any given component within an assemblage is itself an assemblage, identifying a singular cause of any given event is not possible; instead causality is viewed as emergent and nonlinear, where any one effect becomes infused into other causes until cause and effect cannot be separated. Such an approach has clear consequences for the way we approach history and the way we understand change. The influence of new materialism on the ways in which archaeologists come to describe, interpret, and think about change and history is one of the key developing arenas that will define the impact of the theory on archaeology.

Consider Latour's classic example used to explore agency—a man with a gun shooting and killing another person. If we take a mono-causal approach, we might say the man is to blame, he is the cause of the death, and we should imprison him to reduce the risk he poses to the rest of society. We could take an alternative mono-causal approach and say that the gun is to blame and argue that if we reduce the number of guns in circulation we will reduce gun crime. Latour's point is that we need to take a relational approach—it is neither gun nor gun-owner that bring about the death, but the relationship between the two. Arguably, new materialists go further still as they reject singular and linear causation and argue for a role for a wider assemblage of components and their relations. Not only do we need to consider the gun but also the materials the gun and bullets are made of and the ways in which they have made a specific type of killing possible. It is not just the gun or even the bullet that "kills" but the failure of a heart to beat, of blood to reach organs, of lungs to inhale air, of oxygen to reach a bloodstream. Furthermore, the wider assemblage has played a role too: the actions of the deceased and by-standers, the attitudes and beliefs the

man held about guns, about justice and violence, his economic and social background, his job, his family and friends, and his specific motivations. A new materialist approach asks us to pay attention to all the different parts of the assemblage; it does not ask us to weight them all equally, but it does ask us to take them into account.

We can recast Latour's example as an archaeological one to bore into the role of materials further: Consider two people in the Bronze Age fighting with bronze swords. Bronze, as a material, opens up new possibilities—alloys can be melted and recast into a variety of forms in ways that stone cannot. The ability to cast shifts what shapes and types of objects it is possible to make. Metal alloys like bronze have specific properties; the molecules within bronzes can be hammered and cold-worked in order to make the lattice structure of bronze align better and as a result make the metal harder. As people learned of these properties, and began to work in concert with them, through the Bronze Age we see the development of an increasing variety of thinly bladed objects in a variety of forms such as daggers, knives, halberds, spears, and swords. The properties of bronze as an alloy and the understanding of the alloy that people had in the Bronze Age allowed the development of new forms of objects, which shifted what it meant to fight and kill in the period, and the way in which identities were understood. Rather than writing a narrative that focuses on human desire to control the material world, to make better weapons, and to fight, new materialists consider the role the material itself played in changing understandings and practices of combat.

By extending agency beyond the human and adopting a nonanthropocentric ontology, new materialisms have come to significantly question the privilege we give to humans in our explanations of the world. For new materialists, human culture does not master or sit above the natural world; rather it is part of it. This means that we cannot separate ourselves from the worlds we live within, or the worlds that we study. For critics, this recasting of humans as "one of many" and questioning of causality is seen as dangerous as it reduces our ability to seek justice or change the world. Conversely, advocates for the approach argue that only when we fully appreciate the complete cast of interlocking and connected

components in the world, and the complex causality that goes on, can we tackle the complex problems the world faces, such as climate change.

New materialism is part of what has been variously termed the turn to things, the ontological turn, and the material turn. This shift in theoretical stance could be seen as a reaction against the cultural turn, but is perhaps better understood as a supplement to it; it does not necessarily reject outright issues such as identity, meaning, and symbolism, but rather argues that a focus on the cultural without the material is not capable of understanding the complexity of our world.

For those outside of archaeology, new materialism is often framed as a response to the nature of late capitalism, where we are surrounded by the weight of materiality and the difficult ethical and political questions posed by advancing science and technology. Important changes in the way physicists understand the nature of matter have developed alongside increasingly complex and messy understandings about the "boundaries" between life and death. Key new materialist thinkers such as Jane Bennett, Karen Barad, Rosi Braidotti, and Manuel DeLanda draw influence from a variety of sources that include both the hard sciences and the humanities. Many of these thinkers are marked by a commitment to the political—a desire to change the way we conceive of, and shape, the world, often focused around inequality (there is a heavy influence from feminism) and the environment.

In archaeology, new materialism has arguably had the most influence in two forms: the adoption of assemblage theory (drawing on the Deleuzian inspired work of DeLanda 2016) and a re-engagement with materials and their vitality (drawing on Bennett 2010). Assemblage theory is having an increasing influence on archaeological theory (see, for example, Hamilakis and Jones 2017, and papers therein).

Arguably, the engagement with the vitality of matter began for many archaeologist with the work of Tim Ingold (2007), whose early repost to theories of materiality which focused on the human opened the door to approaches that moved beyond anthropocentrism and showed the ways in which materials are always shifting and never static. Ingold's questioning of the "hylomorphic model," whereby making is understood as the imposition of human agency and design on

dead material, has been influential in archaeology. The work of both Chantal Conneller (2011) and Andy Jones (2012) exemplifies the renewed focus on the role of the material in archaeology. Conneller's (2011) work considers the ways in which the properties of materials affect how they are worked and exploited by humans. Her work reveals how different communities have different understandings of the properties of a given material and thereby exploit them in different ways. Jones (2012) argues for the key role materials play in the performance of meaning in prehistory. Rather than viewing materials as simply something upon which human will and meaning are imposed, he argues, through a series of case studies, that the materials themselves played a key role in the creation of meaning in the past. Both Conneller (2011) and Jones (2012) effectively, and productively, bring together the work of material scientists and specialists with archaeological theory.

There are a number of key issues at stake that will affect the future role of new materialisms in archaeological theory and archaeology more broadly. Chief among them is the issue of nonanthropocentrism and the adoption of a post-human ontology. For many archaeologists, archaeology is defined as the study of the *human* past through material remains, and, as such, the suggestion that archaeology should become nonanthropocentric seems an affront to the nature of the discipline (see, for example, the critique in Van Dyke 2015). Nonanthropocentric approaches have also provoked criticism for a perceived failure to appreciate human difference, engage with social justice issues, or consider the role of power in the narratives they write. The radically different understanding of the world that drives the new materialisms, and in particular the place of humans as one-of-many in their ontology, is likely to remain controversial. This problem is compounded by the variety of theories, theorists, and philosophical positions that fall under the term new materialist and

the differing emphases they place on humans, resulting in differing archaeological narratives (see, for example, Witmore 2014 and the response from Ingold). Within the general field there are those that practice a wholly recognizable form of archaeology (see, for example, Conneller 2011; Jones 2012) and others (for example Witmore 2014) who are calling for archaeology to become a radically different subject less concerned with the human past and more concerned with the study of objects.

Perception and Experience

KENNETH BROPHY and
ANDREW WATSON

University of Glasgow, UK

Since the early 1990s, the ways in which people perceived or experienced prehistoric material culture and landscapes both in the past and present has come to the fore in archaeology. Research in this area has attempted to gain an insight into what life may have been like, primarily during prehistory, through our engagement with sites, landscapes, or artifacts in the present day. Before looking at how archaeologists gain an insight into our engagement with such seemingly intangible phenomena we must first define what we mean by experience and perception.

Experience can be defined as the acquisition of knowledge relating to phenomena through our exposure to, and interaction with, the phenomena in question. For instance, the accumulation of knowledge relating to phenomena could be gained through continual exposure to a landscape. By inhabiting the landscape over extended periods of time, and experiencing it at different points of the day, and during different seasons and weather conditions, one might be able to gain insight into how people interacted with this landscape in the past.

Perception deals with our relation to phenomena through the uses of our senses. While studies in archaeology have primarily focused on the visual elements of perception, perception encompasses all of our senses. The combination of sensorial inputs is our perception of a phenomenon, and so, for instance, haptic approaches to material culture have emerged within the discipline. In other words, both perception and experience are contingent on bodily engagement with the object of our study.

The primary approach to this kind of study in archaeology has been through the utilization

of the branch of philosophy, phenomenology. Edmund Husserl is regarded as the first modern-day phenomenologist, with the likes of Martin Heidegger and Maurice Merleau-Ponty building on his work. Each philosopher had their own approach to, and understanding of, phenomenology. In each case, all were concerned with understanding the nature of subject–object interactions and how our material engagement with the world helps us to make sense of them, or ourselves.

In brief, Husserl's approach centered on a desire to get “back to the things themselves” and, through moving perceivers from their natural to phenomenological attitude by means of the transcendental phenomenological reduction, Husserl believed perceivers could suspend their knowledge of the natural world and reduce their experiences of phenomena down to their essential characteristics. Heidegger and Merleau-Ponty both rejected the transcendental approach to phenomenology, believing that our understanding of the world is interwoven with our personal experiences of it and that phenomena can only be understood within the context to which they are unveiled to the perceiver. Through the use of hermeneutics, Heidegger sought to understand a perceiver's engagement with the world through a more interpretative account. Merleau-Ponty, whom many archaeologists use as a starting point, attempted a third way of looking at the world, seeking to break away from the subject–object dichotomy and bridge the division between an empiricist (see *EMPIRICISM*) (Heidegger) and intellectual (Husserl) way of looking at the world.

Here, we define phenomenology as being a descriptive account of a phenomenon as unveiled to, and experienced by, the perceiver. Understanding the essences of our perception and experience allows us to better understand the phenomena. It creates a deeper connection with the phenomena and *may* allow us some insight as to what life could have been like in the past. However, how this might be translated into useful archaeological narratives is much contested.

Insights into how people in the past interacted with monuments and objects through experience and perception are the primary way that phenomenology has been used in archaeology, although it has also been utilized in ontological contexts. Experiential approaches to doing archaeology emerged in the first half of the 1990s in the work of post-processual archaeologists such as John Barrett, Matthew Johnson, Julian Thomas, and Michael Shanks, all of whom were interested in embodied and sensory approaches to monuments in the past and the present, based on the premise that architecture controls bodily movement in socially conditioned ways; exploring or replicating those experiences thus enables an insight into past social conventions, rules, and power structures. Not all of these studies were phenomenological, but all explicitly relied on an embodied and engaged approach to experiencing Neolithic monuments or castles, as opposed to traditionally used approaches (such as access analysis and map work) which depended on a detached stance.

The first attempt to set out a detailed theoretical and methodological framework for phenomenological experiential approaches was undertaken by Christopher Tilley (1994), who argued that archaeologists could “suspend their knowledge” when in the field, and give primacy to the role of the body and the senses in navigating and interpreting archaeological sites and landscapes. Drawing on philosophers Heidegger and Merleau-Ponty, Tilley established “landscape phenomenology” as a fieldwork methodology, illustrated through a series of extended case studies drawing on walks and personal accounts of the impact experiences with Neolithic monuments and their localities had on his senses and body. Subsequent refinements of this method broadened the temporal and material boundaries for the use of phenomenology in archaeology, but in essence Tilley’s approach involves giving primacy to subjective perceptual observation as a means by which past motivations and experiences can be evoked. The process ends with interpretation of the experience of body and senses of the archaeologist: “drawing together all these observations and experiences in the form of a synthetic text and imaginatively interpreting them in terms of possible prehistoric life-worlds ...” (Tilley 2008, 274).

Tilley’s landscape phenomenology remains a dominant and influential means by which perception and experience may be used in an archaeological context. Approaches that draw on sensory perception inspired by Tilley’s project have been much imitated, sometimes uncritically, but more often with various modifications, checks, and balances. The primary use has been to study Neolithic monuments across Europe, although phenomenology has also been applied to later prehistoric enclosures, Roman sites, castles, and historic landscapes. Proponents of such experiential approaches include Vicki Cummings, Aaron Watson, and Alasdair Whittle, with much of this research emerging within a northwest European context.

Experiential approaches to studying the Neolithic have been subject to sustained critique (Brück 2005). Fleming (2006) has been critical of the levels of rigor and repeatability within such fieldwork, while the nature of the interpretations made are problematic due to an inability to demonstrate causation, and contemporary bias towards the sense of vision. Barrett and Ko (2009) and Thomas (2006) have argued that landscape phenomenology misunderstands the phenomenological basis for the methodology and as used by Tilley is merely a means to walk about, describe what one sees, and interpret the results within specific historical conditions. These issues, as well as accusations of solipsism and modern-day antiquarian indulgence, and a recognized lack of sufficient granularity in environmental information to adequately replicate prehistoric landscape conditions, have helped modify, refine, and mitigate experiential approaches within archaeology, most recently with the use of digital technologies and geographic information systems (GIS).

Experience and perception have not been restricted to landscapes and monuments. Thomas has argued that “ideas of the phenomenological traditions have been highly influential in the study of material culture” (Thomas 2006, 43). Approaches that foreground how we use, interact with, and are stimulated by materials around us such as experimental archaeology, haptic studies, and approaches that consider the manufacture and use of objects subvert typological empirical studies by foregrounding experience and sensory engagement with things.

Experiential approaches to monuments, buildings, landscape, and material culture are now commonplace in archaeology and to an extent a given, having evolved beyond the theory-laden approaches prevalent in the 1990s and 2000s, and with less emphasis on the philosophy of phenomenology. Concepts such as a sense of place, biographical and spatial approaches to landscape, and issues related to materiality and the elements have all emerged because of the experiential turn in archaeology in the early 1990s.

While phenomenological investigations have been undertaken within archaeology since the late 1990s, as of yet there is no widely accepted methodology or guide for best practice. There are, however, several approaches that allow us to gain an insight into how people may have perceived and experienced prehistoric objects, sites, landscapes, and monuments.

Perhaps the clearest defined methodology for experiential archaeology has been refined since the early 1990s by Tilley. In *A Phenomenology of Landscape*, he introduces a first-person account of walking the landscape by means of the Neolithic Dorset Cursus in southern England (Tilley 1994, 173–196). For Tilley, walking allowed him to begin understanding the position of monuments within the landscape, looking at views to, and from, a monument, partially replicating prehistoric bodily experiences. What his account lacks is any clear fieldwork methodology or structure for recording his experiences. Hamilton et al. (2006) provide a more robust and structured method for walking a landscape by means of their phenomenological site catchment analysis (PSCA). PSCA participants walked one hour in each cardinal direction noting changes within the landscape and ground conditions using recording pro forma; experiments with group participation were attempted, as well as a gendered reading of results. This methodology also incorporates the use of 360° diagrams, the use of which is adapted from Cummings and Whittle's 2004 study of barrows and landscapes in Wales, and drawn by participants in order to record what they could see from a set location (usually an archaeological site), and establish patterns, although such devices prioritize visual perception.

Other sensory experiences have been given less attention. Hamilton et al. (2006) sought to understand how everyday sounds and smells may

have been experienced within Neolithic ditched enclosures, while Keating and Watson (1999) have researched the sensorial effects of sound within passage graves and stone circles, part of a growing field of archaeoacoustics. In these examples, the potential experience and impact of sounds in domestic and ceremonial contexts were considered, with, for instance, percussive sounds within megalithic tombs potentially having physical and psychological impacts on participants, causing altered states of consciousness.

The approaches and studies above do not claim to provide exact accounts of the experience of prehistoric people, but instead look to give an insight into how people may have inhabited landscapes (see *INHABITED LANDSCAPES*), or experienced monuments, during their time of occupation. Furthermore, as the experience of a landscape is different to that of a tangible object, the approaches to each phenomenon will inevitably be unique and personal. The value of such approaches, which happen in contemporary settings, remains open to discussion, but it is clear they offer a different perspective, open new lines of enquiry, and have been deeply influential.

Personhood and Objecthood

JULIE LUND

University of Oslo, Norway

Within archaeology, a study of personhood may focus on what or who was considered to have the capacity of being *a person* in a given historical context. It examines how and in what manner *a person* was produced and articulated. Just as personhood relates to the state of being, or being regarded as, a person, objecthood describes the state or condition of being an object. In art studies, the term *objecthood* is applied, more specifically, as the opposite of *art*, from the art historian Michael Fried onward. The concept of personhood is also applied in psychological and philosophical studies of self and identity, and in law in relation to issues of rights (such as animal rights, etc.).

More than anyone else, Chris Fowler has introduced the study of personhood in archaeology (Fowler 2004). Fowler builds partly on the ethnography of Marilyn Strathern and Janet Hoskins and on Marcel Mauss's theory of reciprocity and gift giving. Ethnographic studies have demonstrated that very intimate links between the life stories or biographies of individual humans and objects may be produced. Strathern points out that gifts *are* relations, which means that, through gift giving, the social biography of objects and humans become interwoven (Strathern 1988). Personhood is fundamentally linked to relationality, in varying degrees and forms. Ethnography can be used to identify the multitude of ways in which personhood may be constructed in a given context, time span, or setting. In particular, the concept of *dividual* versus *individual* personhood has been highlighted in these studies. Whereas *individuality* is emphasized as part of modern, western concept of personhood, other cultural contexts, past and present, may be dominated by the idea that persons are not bounded but partible; a person

is a composite being, produced and expressed through actions such as gift giving (including the marriage exchange). A dividual person thus emerges from the relations *between* humans; and such a person may consist of substances (such as gifts) that are transmitted from one body to another (Strathern 1988).

Whereas a study of identity may investigate diverging and overlapping social roles and social interaction, a study of personhood aims at examining questions of *ontology*. Studies of personhood have been criticized for relying too heavily on specific ethnographic models. However, it is crucial to understand the ethnographic parallels as models that are what Claude Lévi-Strauss would qualify as *good to think with*. They are alternatives to a modern, western concept of personhood dominated by the idea that one human body equals one individual, which in turn equals one person. The study of personhood is thus not a theory to be applied to the archaeological material, but a way in which one may approach that body of material and raise research questions.

Within archaeology, the study of personhood has been of particular interest to research on Neolithic and Bronze Age Europe. Such research includes studies of the construction and deconstruction of personhood, as examined through analyses of fragmentation and wholeness in relation to burial customs and acts of deposition. As Fowler points out, a general feature found in many religions is the concern for the fragmentation of a person following death. In acts related to burial we find many examples of attempts to either preserve the integrity of the body or accentuate its fragmentation. In other words, burial acts underline cultural themes related to personhood. Research on personhood has actuated a stronger focus on the parallels between the way bodies and objects are treated, handled, and marked; recent studies have indeed clearly demonstrated the *changing* character of personhood in different cultural contexts. These alterations of personhood are also identified in relation to change of religion. For instance, the burial customs of the Viking age show the largest degree of variation

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

DOI: 10.1002/9781119188230.saseas0448

observed in any prehistoric period of Scandinavia. These pagan graves contain profound examples of fragmentation and destruction of the body, but also burials that show extreme care to preserve the wholeness of the body and the grave goods. This changes with the advent of Christianity in Scandinavia: after this conversion the burial customs are still highly divergent, but all consists of *whole bodies* with *whole objects* in them, which points to a parallelism in the way bodies and objects were treated.

In many cultural contexts, be they of the past or of the present, personhood is not considered to be restricted to human beings, and concepts of objecthood diverge from modern western ideas of what an object is. Studies of human–animal relationships have showed that the modern western notions of personhood and objecthood may not be representative of past societies. In numerous circumpolar contexts, it is not solely human beings that are considered *persons*, but other types of beings as well, for example stones, trees, and animals. Among the Siberian Khanty, humans, animals, water running in a river, falling snow, or thunder are considered animate, whereas snow that has fallen, water in a bucket, or a rock that cannot be moved are considered inanimate objects (Jordan 2003, 103). These types of categorization of what it means to be a person or an object are also found outside the circumpolar areas, mainly among hunter-gathers such as in the Amazon, which shows noticeable similarities to the circumpolar examples (Brightman, Grotti, and Ulturgasheva 2012), and in the Andes (Sillar 2009).

Benjamin Alberti studied La Candelaria anthropomorphic vessels from Northwest Argentina—or what he terms *body-pots* (Alberti 2007). Instead of seeing these objects as *representations* or *symbols*, one may understand them as beings in their own right: not as humans, but as persons. Personhood may also be identified in archaeological contexts where objects were treated as if they were human bodies, since they had the same *capacity* as a human body. For instance, in a number of Norwegian cremation graves of the late migration period, a single bucket-shaped vessel, a unique object type, was placed in the grave and used as container for the deceased bones. While the vessel replaced the human skin, the person was preserved

through the transformational act of the burial (Fredriksen 2006). Such a perspective departs from interpreting these objects as mere *representations* of human bodies. In many contexts, the personification of the object or a feature in the landscape is understood as *occurring* in specific situations. Thus, one way of approaching personhood versus objecthood may be to turn our attention to objects and landscape features that, in specific cultural contexts, were treated, handled, and categorized differently from objects and landscape features in general. It must be recalled that this by no means implies that all animals and objects are considered as having personhood. Noticeably, in ethnographic studies of animistic hunter-gather societies, personhood emerges *in the given context of a specific time and place*. A tree or an animal is not considered to simply *take the role* of a person, but to *be* a person. This implies that a western ontology of personhood is not necessarily applicable to other cultural contexts. Put another way, the ontological duality of nature and culture might not be relevant if we aim at understanding the mind-sets, worldviews, and ways of life of people from outside a modern or postmodern western world—and perhaps not even from inside it.

The study of personhood also relates to the concept of animism, because in animism specific natural features, animals, or objects may be considered to possess personhood. However, studying personhood is not in any way limited to societies with an animistic religion. Phillip Descola presents four different types, classes, or basic sets of ontologies, and one of them is an animistic ontology; but he points out that these ontologies, different as they may be, are not mutually exclusive (Descola 2013, 129–43, 231–3). Thus, even though people in western societies may treat their pet, their car, or their leather jacket as if it possessed personhood, that is not the expression of an animistic religion. As the social identity of objects is linked to the chains of social relations to and among humans through the social life of the object, the biographical perspective partly coincides with these perspectives on animism. In animism, reciprocity is a central element in the relationship between humans and objects, or humans and places. In the Andes, for instance, offerings and daily work

are used to develop reciprocal social obligations with animated objects and places. In this process humans create social relations with the material world. Furthermore, this relation imbues the implicated artifacts and places (Sillar 2009, 367–74).

New perspectives on objecthood have been brought to the fore by the so-called object-oriented ontology. Whereas the studies of personhood have a focus on potential agency (be it primary or secondary), object-oriented ontology rejects anthropocentric positions by placing emphasis on the fact that reality exists without human beings. Instead of examining only the effect objects have on humans, object-oriented ontology focuses on objects themselves, including their effects on one another. This position has developed in philosophy and has had a significant impact on contemporary art. Just like the research on personhood, these object-oriented approaches have had their focal point in ontology. One position that has absorbed these perspectives on objecthood in particular is symmetrical archaeology. The ontological turn has also been widely debated in anthropology, but object-oriented archaeology has emphasized the methodological differences between archaeology and anthropology; archaeology, in contrast to anthropology in practice, is (at least partially) a study of objects in which archaeologists, through the practice of excavation, engage with the material world in very specific manners. In symmetrical archaeology a key issue is that humans and nonhumans should not be regarded as ontologically different entities. Instead every being in the world can equally be seen as a differentiated thing (Olsen and Witmore 2015). Symmetrical archaeology has challenged the a priori anthropocentric stance of archaeological research. These perspectives have primarily been used in studies of contemporary archaeology. They focus on the qualities that objects or entities have and on the relationship *between* things, including the entanglements and assemblages of things (see Olsen and Witmore 2015, with references). Correspondingly, other studies have emphasized entanglements of humans and objects and the creation of entities in assemblages. By paying attention to the importance of *relations* between things and to the (continuous) construction of

entities consisting of objects and relations respectively, these studies have created new perceptions of objecthood. The turn toward objects has also been used to revitalize discussions in heritage studies on materiality, as even discarded, superfluous, and unwanted objects may be preserved through generations, thanks to their material persistency. More importantly, in ethics it has opened up a debate on whether things should be granted certain rights, including the right to decay (Pétursdóttir 2012).

Philosophy of Science

WILLIAM H. KRIEGER

The University of Rhode Island, USA

The philosophy of science

The philosophy of science is a subfield of epistemology, an area of philosophy that asks questions about the nature and limits of knowledge. Science focuses on a set of theoretical and methodological tools to study the natural world; and the philosophy of science studies the processes that lead scientists forward in their pursuit of knowledge. As in most philosophical disciplines, philosophical questions about science go beyond the stated expectations of their field of study. Here philosophers focus on the relationship between science and knowledge, on the goals of science (or of individual sciences), on the methods of science, and on the relationship between scientific theory and practice.

Perhaps ironically, the philosophy of science as a field has an indeterminate origin. Before the 1800s what we now think of as science was, to a large degree, tied more closely to answering philosophical questions than it was to experimentation. In fact, many early practitioners were called “natural philosophers.” The paradigmatic, lab-coat-wearing experimentalist is a product of the modern era, and indeed the name “scientist” was only given to this group (and to the world) in 1833 by William Whewell. As a result, there are those in the philosophical (though no so much in the scientific) community who question whether pre-nineteenth-century activities should be considered science (and whether their study should be founded in the philosophy of science). That being said, many philosophers of science specialize in medieval and ancient “science,” and, even among contemporary period philosophers of science, most agree that the tools used by philosophers of science can be applied to the ancient, medieval, and modern

worlds as readily as they are to the contemporary world.

Setting aside origin stories, traditionally the philosophy of science focuses on a number of core areas, namely questions concerning the separation of science from nonscience (the demarcation problem), questions about the theoretical foundations of science (explanation and confirmation), and questions surrounding the workings (methods) of science. As we will see here, each of these issues is as open a topic in archaeological circles as it is to philosophers. However, many in the archaeological world are unaware of the existence of these philosophical issues and, sadly, philosophers are generally also unaware of the work archaeologists have done to address them.

The demarcation problem asks where we are justified in drawing a distinction between fields that should be considered sciences and fields that should not. This job is difficult because there is no simple litmus test to divide science from nonscience. If we argue that science, unlike nonscience, is true, then we have to explain why Newton was not a scientist (as he was wrong about many things). Additionally, arguments based on the existence of data fall flat, as multiple fields, some of which are sciences (such as chemistry) and others decidedly not (e.g., alchemy), might share the same data set. Further, fields can gain or lose their scientific status as our ideas about science change, as was the case with parapsychology, once regarded highly enough as a science to command a section in Alan Turing’s 1950 paper on artificial intelligence, but now regarded as pseudoscience.

Perhaps the easiest way to demarcate science from nonscience would be to ask for a strict definition of science. However, sciences range in their focus from the strictly theoretical to the ultimately practical. They take place in the laboratory or in the field. They hold sway over matter subject to determinism or free-willed humans. This being the case, attempts to give a singular, unified definition to science have, to date, been

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

DOI: 10.1002/9781119188230.saseas0450

largely unsuccessful. In response, some philosophers have offered solutions to the demarcation problem by creating lists of scientific criteria or desiderata, in other words Schick and Vaughn's (2013) testability, fruitfulness, scope, simplicity, and conservatism. Others see science as the means to understand how individual acts can be viewed as examples of universal laws (Hempel 1966). Still others show how easily science can be ruined by overconfidence and propose that the only real way to see whether something should be considered good science is to subject it to grueling tests designed to make it fail (Popper 1963).

Of course, every one of these options carries with it different assumptions about what scientists are doing when they don their white lab coats. When philosophers ask questions about the fundamental goals of science, these questions fall under the headings of explanation and confirmation. Scientists appeal to explanation in order to answer "why" questions (e.g., why my pencil drops to the floor when I release it from a height of two meters). To answer such questions, early scientists focused on inductive methods in their scientific approach (appealing to the relative sufficiency of evidence as a standard for scientific arguments). Others, including Hempel, believed that sufficient proof is not enough as a grounding for scientific certainty, arguing instead that science is, at its best, deductive (it appeals to logical certainty as the standard of evidence for arguments). Throughout his career, Hempel argued that the goal of science is to go beyond what he called "mere description." Instead, science should have as its purpose the explanation of phenomena. According to his account, explanations are the byproduct of using logic to ground scientific observations in universal laws. Once an observation is properly encoded, a scientist can not only explain a past observation but also predict its next occurrence. For instance, there is a real difference between documenting a pencil's falling and explaining its occurrence. By understanding the universal laws at play (gravity, friction, etc.) and the facts on the ground (a pencil being dropped from a height of two meters), I could explain the fall of the pencil, predict future falls, and show that other objects of similar mass and similar relevant physical properties will behave in the same way.

Once these explanations are set out, they can be put to the test, either against themselves or against other possible explanations. This activity is called confirmation; and, together, Hempel's models of explanation and confirmation were used to provide a foundation of certainty to scientific inquiry. If science is based on logically connecting individual events to universal laws, scientists would be able to fully understand the world, make certain predictions about the future, and fully confirm their hypotheses.

Unlike in the traditional "law and order" approach to science, other figures have argued that science cannot get to the truth of the matter by focusing solely on universal laws. According to Cartwright (1983), while laws may play a necessary role in explanation by setting order to chaos, we have no way of knowing whether these laws are truly real or universal. Kuhn (1962) argued that scientists divide the world up to answer questions that interest them, and create laws to help make sense of these divisions. For Kuhn, understanding the material behind our decision making is paramount if we are to make sense of scientific practices. Kuhn argues that scientists are a community that shares a worldview: literally, a particular way of understanding their topic, also known as a paradigm. This common language and understanding of the world is a precondition or a foundation for science. Paradigms unify a field, allow progress, and determine what is or is not to be considered science. It is only after we know which questions are good scientific questions that we can engage in the activity of doing science, an activity that Kuhn calls "normal science" (or puzzle solving).

While Kuhn founded science within the workings of the scientific community, other philosophers of science pushed back even harder against traditional science, arguing that shared worldviews cannot simulate objective truth; this led to an "any explanation goes" world. While some believe that the world itself is quite capable of telling us which explanations are plausible and which ones should be dropped, others, including Feyerabend (1975), have argued that, since shared worldviews are subjective, science itself is just a subjective ideology.

In order to unpack this problem, we need to look more closely at the worldview material undergirding our science. To some, this means

focusing on our values as scientists. “Science and values” questions ask about the impact our values (needs, desires, etc.) have on our science. Granted, not all values are considered appropriate to all scientists. While logic and certainty are considered to be perfectly acceptable epistemic values by the scientific mainstream, other, nonepistemic values may also play a part in our science. Sometimes this is a good thing. We value preventing suffering. So, for the most part, we do not run experiments that knowingly cause suffering in our test subjects. This is a choice that we make, however, and it does have consequences. There have been periods in history when the scientific community has questioned whether it should be able to use the data taken from inappropriate scientific experiments (experiments involving torture, genocide, etc.). Scientists in favor of using those data make arguments that saving lives now is more valuable than the value we place on doing and participating in responsible science. In other cases, scientists have to deal with unconsciously held values, ones that may or may not be truly detrimental to good scientific practice. For example, we could ask whether our views on gender shape our science. Or is it mere coincidence that science is defined by objectivity and reason, traits associated with the dominant group of scientists in the twentieth century—men? Similarly, those of us who live in the United States are certainly lucky, as capitalism (which focuses on individual discovery and competition) just happens to match up with the way in which we believe science “must” be done.

Philosoph(ies) of archaeology

Although there are people in the field who question whether archaeology should be characterized as a science and place it rather within art history or classics, most of the theoretical work from the mid-twentieth century to the present, the explicitly scientific nature of contemporary archaeological methods, and the existence of archaeometry (see *ARCHAEOMETRY*) as a field provide sufficient reason to argue that archaeology is itself a science. Furthermore, archaeologists working with artifacts and biological or environmental material benefit directly from work done

in other scientific fields (e.g., physics, geology, chemistry, biology, and anthropology). Fortunately, archaeologists have engaged, whether consciously or not, with many of the theoretical issues that dominate the philosophy of science. Hence the remainder of this entry will focus on connections between the philosophy of science and archaeological science.

Archaeological explanation and confirmation

While archaeology is, in one form or another, one of the oldest of disciplines, archaeological science is young. Before the mid-twentieth century, the goals of archaeology were associated with new ideas about culture that were coming from anthropology. That theoretical basis, called culture history, had as its goal the identification of distinct cultures or ethnicities by tying them to specific types of artifacts (material culture). Once a culture group was identified and established, it was believed that that group would remain stable and that cultural change (evident from changes in material culture) occurred through migration, diffusion, or invasion. In order to tie material culture to culture, Culture historians argued that a particular ethnic group could be inferred from, or associated with, a particular assemblage. They created master lists of ceramics, building styles, domestic animals, and even foods, and used these data to identify a site as belonging to a particular “people.”

Certainly, creating catalogues and understanding typologies is still important (and collecting archaeological materials remains an important part of fieldwork). However, a group of twentieth-century archaeologists argued that there must be more to archaeology than the cataloguing of finds. Abandoning the idea that cultures are rigid and easily distinguished through differences in diet, floor plans, or burial customs, these archaeologists, for example Binford (1962), believed that culture change is much more fluid. Binford had been reading contemporary work in the philosophy of science, and Hempel’s model of explanation and confirmation seemed like a good fit for this “new archaeology.” As argued by Krieger (2006), the new archaeology—later

renamed processual—attempted to map archaeology onto Hempel's nomothetic model of science. Processual archaeology would explain (and not just describe) the past by rooting archaeological fieldwork in general laws and deductive logic. Unfortunately, the new archaeology was unable to deliver on its promises. While the field attempted to set archaeology on the path to certainty and predictability, in the end, it got bogged down in the same systemic problems experienced by philosophers (asking whether useful universal laws of archaeology exist, questioning whether archaeological artifacts can be connected to modern explanations, and the like).

Critics of Hempelian processual archaeology, called postprocessualists, come in many forms, but they are united in rejecting the idea that the data are somehow objective arbiters of truth as well as processualism's narrow, law-based approach. In this rather Kuhnian view, also taken up by Marxist and feminist archaeological perspectives, archaeology can serve many purposes, depending on the worldview and goals of the excavator and sponsoring institution. Consequently, postprocessualists might focus on interpretations of data that favor underrepresented groups or tell multiple, potentially conflicting stories about a site, or they might decide to ignore archaeological data (as those data are going to be deposited by dominant groups) in favor of oral histories collected by the modern inhabitants of that site.

While it is true that culture history was replaced in the theoretical literature in the 1970s by processual archaeology, which was then attacked by postprocessual archaeology about twenty years later, this theoretical battle only exists on paper. Each of these positions, when removed from the hyperbolic rhetoric that makes for good academic papers but for lousy archaeology, contains a lot of potential for nuance and rapprochement with other positions. Just as we see in the philosophical literature, Hempelian-style (processual) and Kuhnian-style (postprocessual) archaeologies have evolved, incorporating materials from each other and making sense of the data in ways that best serve their values. Perhaps more interestingly, in the field, processualism and postprocessualism (and culture history) do more than exist: they coexist, as archaeologists, unconsciously or intentionally,

apply each epistemological foundation where they need it in order to address a particular sort of question. Fieldwork involves a huge amount of finding and cataloguing artifact typologies (culture history). Those findings are then routinely used in trying to learn about regional changes: large amounts of data are used to make us understand general trends about the site, region, or time period (processualism). Multiple perspectives are employed in order to construct and deconstruct canonical understandings of a particular ancient society by focusing on groups other than elites, such as the poor, slaves, minority groups, and the like (postprocessualism).

New archaeological frontiers in philosophy of science

While traditional questions about the nature of science play themselves out in archaeological circles, newer questions about the nature and limits of science have led philosophers of archaeology to bend the limits of their field. For instance, First Nations and other indigenous groups have challenged archaeologists' claims to the "ownership" of archaeological sites, artifacts, and remains. Where in some sites "traditional" archaeologists have fought to keep control of those sites and of their data, other archaeologists have instead engaged with native groups (see PUBLIC ARCHAEOLOGY). While deciding whether to create partnerships with local landowners seems like a purely political decision, deciding (as some have) to share curation of their data with oral historians and local communities and including outside interpretations of archaeological data in publications and excavation reports demonstrates how central epistemological issues are to these scientists. Recognizing the importance of collecting data about artifacts in context (which is crucial to an artifact's ability to be used as a piece of scientific data) but cognizant of the financial and political impact that archaeology has on peoples who live at (and off) a site, archaeologists are engaging with local subsistence diggers to find ways to preserve data and local lifeways while fighting the international black market.

Archaeologists are also looking to repurpose their data, employing new theoretical models

to break down the barriers between past and present. Where culture historians or processual archaeologists might have collected data for their own site (or maybe for larger regional studies about trade patterns), open access to archaeological data has allowed other groups to study, remix, and reinterpret old findings. Environmental archaeologists are also experts at sharing data, using material from ice cores and tree rings, appealing to climate scientists for their models, and then using those models to demonstrate the impact of environmental change on societies throughout time.

Positivism

AMPARO GÓMEZ RODRIGUEZ

Universidad de La Laguna, Spain

Archaeologists have paid close attention to the philosophy of science in their search for epistemic and methodological grounds for their discipline. They have developed, within the archaeology realm, an interesting epistemic and methodological reflection. As Wylie (2002, xii) recalls, the training of young archaeologists included philosophy of science as well as specific research techniques.

Positivism, both in its nineteenth-century form and, particularly, in its twentieth-century neopositivist version, was a philosophical school of thought that played a key role in reflections on the nature of archaeological knowledge, as well as in the development of archaeological research approaches. It was at the heart of efforts to establish archaeology as a scientific discipline and has been the adversary with which the different post-positivist philosophical perspectives of post-processual archaeology have had to contend.

In the nineteenth and early twentieth centuries, the aim of North American archaeology was to gather as much data as possible in order to understand the past. Archaeology was a descriptive, taxonomic and inductive discipline linked to stratified chronology. The task of archaeologists was to establish data based on empirical observation, not to formulate laws and explanatory theories. Rather, they limited themselves to describing individual facts, on the basis of which they formulated stories to understand specific cultures.

In Europe, cultural narratives were explicitly interpretative in line with German historicism. Archaeology was part of history and, as such, interpretative prehistory. Archaeologists elaborated reconstructions of the past which were assessed according to the proponent's prestige (according to Thompson's authority argument (1956, 331), we evaluate reconstructions or interpretations by evaluating the competence of the person who is proposing the reconstruction).

These trends dominated the field of archaeology until the 1940s and 1950s, when they were called into question, mainly by North American and British archaeologists. To differing degrees, these archaeologists were advocates of neopositivism, which had emerged at the beginning of the twentieth century thanks to the work of Carnap, Neurath, Hempel, Nagel, Rudner, and Wallace, among others (including, of course, the Wittgenstein of the *Tractatus*). The basic aim of this philosophical movement was the analysis of language using mathematical logic. But it was mostly the neopositivist epistemology and methodology that archaeologists decidedly adopted. Consequently, between 1960 and 1980, the neopositivist epistemic approach was quite influential within the field of archaeology. Thereby, scientific research was considered neutral and objective, and expressed in observational language on which hypotheses and theories were tested—through either verification or, at the very least, confirmation. Observational and theoretical language constituted two different spheres; therefore, the terms used in each should be of a completely different nature. Finally, scientific explanation was based on laws according to Hempel–Oppenheim's deductive–nomological model—although inductive–statistical explanations were also considered scientific.

This was the epistemology of the “new archaeology,” also called processual archaeology, which constituted a dominant “research program” until the emergence of post-processual archaeology during the late 1980s. New archaeology first took form in a number of papers published after World War II (pioneering works included those written by Willey and Phillips (1958) and Taylor (1948)). The approach was later developed through the work of a group of archaeologists, headed by Binford (1962, 1968, 1977, 1979, 1987), with authors like Clarke (1968), Flannery (1968), Fritz and Plog (1970), Renfrew (1987), Watson, LeBlanc, and Redman (1971), among many others.

The basic thesis of this archaeological movement was that archaeology was not the mere descriptive study of archaeological sites, neither

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

DOI: 10.1002/9781119188230.saseas0471

was it an interpretative history, as traditional archaeologists maintained, but rather science. As a science, archaeology was related to anthropology, of which it could be considered a branch—hence Willey and Phillips' (1958, 2) well-known rephrasing of Maitland's famous dictum: "American archaeology is anthropology or it is nothing."

Therefore, archaeology was considered a general science, based—just like any science—on observation, measurement, experimentation, generalization, and explanation. Since it was possible to objectively know the past and its laws, it was also possible to explain it and verify scientifically all this knowledge. While traditional archaeology focused on understanding specific cases, processual archaeology saw each individual case as being related to research of general issues. Binford described the new program in very clear terms (1968, 274): "We seek to replace these inadequate propositions with laws that are validated in the context of the epistemology of science, so that we may gain an accurate knowledge of the past."

The material base of new archaeology was archaeological records (see *ARCHAEOLOGICAL RECORD*), which contained direct and objectively observable, classifiable, and, therefore comparable, material remains. Although the cultures of the past had disappeared, they could be researched, since archaeological remains were records that could be observed and investigated. Thus, archaeologists organized their data and established typologies, taxonomies, temporal series, and integrative units (Willey and Phillips 1958, 5, 29–31). From these data, it was possible to infer facts and reconstruct the past processes, even though these processes could not be *directly* observed by archaeologists. This implicated formulating hypotheses regarding cultures' underlying processes, comparing them with those of other cultures, and generalizing. These hypotheses were checked by researching the material available in the present, and if they were verified, they became laws.

Processual archaeologists believed that research should focus on the organization and adaptive properties of cultural systems. The material remains found in archaeological sites were produced by societies that made up cultures, mainly as an adaptive response to the natural environment in which they developed. And, as

Binford (1979, 271) pointed out, "the research process therefore starts with the construction, usually from (cross-cultural) ethnographic data (see *ETHNOARCHAEOLOGY*), of a hypothetical cultural system and deduces the consequences of its regular functioning for the archaeological record." Culture is viewed as the extrasomatic means of adaptation for the human organism. Thus, new archaeology was not interested in the insides of action or the symbolic aspects of the cultures of the past (which were of interest to post-processual archaeologists), but rather in environmental determining factors, general mechanisms, and collective behavioral patterns. This is what enabled archaeology "to speak with greater authority and accuracy about the ecology of past societies, their technology, their economic basis and their social organization" (Renfrew 1987, 6).

Systems theory and evolutionism were the large-scale theoretical frameworks of processual archaeology. However, empirical research was not directly conducted from these broad frameworks, but from middle-range theories (MRT). MRT were formulated by Merton in the 1960s and were introduced into archaeology by Binford (1977). These theories were linked to empirical research and were located mid-way between observed empirical data and general theoretical frameworks. MRT enabled archaeology to be considered an experimental science. Processual archaeologists also used modern tools such as set theory, mathematical topology, the analysis of new geography, statistics, and computing (indeed, they were pioneers in the use of computation).

On the other hand, the processualists believed that researches showed that many innovations or cultural changes arose independently in a number of different, unrelated places, as well as at a number of different moments. Thus, they detected certain equivalences between existing "primitive" cultures and cultures of the past which occupied the same social-cultural and ecological niche. Analogies could be established between these two types of culture, and facts and processes could be inferred about the latter on the basis of research into the former. Analogies enabled general, verifiable hypotheses to be established, which, when proven, would become laws.

Laws were essential, since any archaeological explanation should be based on confirmed universal laws. The deductive–nomological model, which was based on covering laws, was considered to be the scientific explanation par excellence. This model was deemed to be the basic structure of any explanation. When no universal laws could be established, Hempel's inductive–statistical explanation could also be used.

As the 1980s progressed, the positivism of processual archaeologists gradually became more refined. There was an acknowledgment that the observational events in which archaeologists participated were partly the result of what they deemed profitable to observe. As pointed out by Binford (1987, 393), “Putting this situation very bluntly, all archaeological data are generated by us in *our* terms.” The existence of auxiliary hypotheses connecting data with the hypothesis to be confirmed through interpretations of these data was also accepted. But interpretative hypotheses should be confirmed; thus, if it is possible to conclusively confirm hypotheses of this kind, they could act as a premise of a deductive argument about that, given a particular kind of archaeological record, and certain specific conditions and events that must have occurred in the past.

However, processual archaeologists were extremely critical of post-processual archaeology and the various philosophical schools of thought that constituted it. They questioned the subjectivism, relativism, conventionalism, and textualism of these perspectives, along with their conception of culture as a system of intersubjective meanings involved in the actions. They also questioned the radical recourse to hermeneutics, that is, the idea that access to artifacts is determined by an adequate understanding of cultural context, and the consideration that archaeologists' observations were pre-intellectualized understandings, just as in the case of ethnographers and their intercultural experiences. Processual criticism highlighted the similarities between these positions and those adopted by traditional archaeology.

Processual archaeologists continued to maintain that recourse to experience was a key part of archaeological research: “At this juncture the scientist is responsible for seeking out experiences

as widely as possible in order to provide reality checks on the accuracy and utility of his ideas” (Binford 1987, 62). They did not stop believing that experience was independent from the hypotheses, that the external world existed—including the properties of archaeological records—and it was scientifically cognizable. They continued to propose explanations regarding the nature of the organizations of the past and how and why they changed. Thus, the fundamental aspects of processual archaeology remained active, despite the nuances introduced by the increasing influence of post-processual archaeology.

Quantification and Social Life

MARK ALDENDERFER

University of California, Merced, USA

Quantification, measurement, and the quantitative idiom

Despite real differences among the theoretical approaches used by archaeologists to conceptualize the past, our research nevertheless is fundamentally concerned with understanding the social lives of past peoples. We seek to take the “static” archaeological record—the materials recovered from surveys and excavations—and translate them into the “dynamics” of a once vibrant cultural system.

“Social life” covers a great range of behaviors, structures, and processes; it includes everything, from foraging choices to kinship and from the division of labor to household consumption, political economy, and the formation of complex polities. As societies become more complex, the relationships between social entities become richly entangled and this significantly challenges our interpretative frameworks. Quantitative methods of all kinds have long been thought to be important tools in untangling these relationships.

Quantification is essential to archaeological inference and deals with numerical descriptions of empirical situations (Johnson 1978). Quantitative analysis involves the use of some method to manipulate numbers and measurements. Although critical theorists decry quantification as an inherently political act that strips the data of most of their meaning, it is difficult to see how comparative research of any kind could proceed without it.

The most basic form of quantification is counting, which implies that some sort of classification of the material recovered during the research process has been developed. Comparing counts and proportions of materials across stratigraphic

levels, contexts, and sites is compatible with every theoretical orientation, except those that take a radically critical perspective.

Measurement is related to quantification and is the assignment of numbers to an object or process according to some rule that is in common agreement among the scholars in the field. The units of measurement are not important as long as there is agreement on the measures and, importantly, on the procedures by which the measurements are obtained. Simple examples are taking the physical dimensions an object in inches, centimeters, or rods, or assessing the chemical composition of a ceramic vessel by parts per million. Measurement is important because it gives us access to mathematics, which offers a rich body of methods ranging from arithmetic to the calculus and beyond. Mathematics provides the tools by which more complex forms of quantitative inference can be employed to model and interpret the past.

Obviously, measurements must be meaningful—that is, they must bear some reasonably sound relation to the phenomena being described or modeled. Meaning is derived from previous experience or theory, and these provide guidance on the selection of things or attributes to be counted and quantities to be measured, and on the complex interrelationships between variables thought to be important to the process under assessment. Good measures may lead to more productive insights or more successful models, but it is often the case that what is chosen to be measured is selected on an ad hoc basis, just because it is possible, and not necessarily because it is carefully linked to the phenomena under analysis.

The definition of a robust quantitative idiom is perhaps the most critical aspect of how one reasons about anthropological or archaeological phenomena with numbers, statistics, or mathematics. A quantitative idiom is more than simply plugging numbers into a statistical formula or solving a series of differential equations; it is instead a recognition that *thinking* about some phenomenon using numbers is likely to

be productive (Aldenderfer 1987). Dwight Read (1987) offers a useful way of assessing the degree to which any quantitative idiom is robust. He describes well-defined (WD) or poorly defined (NWD) populations, and well-defined (WD) and poorly defined (NWD) variables. A WD population is one in which variability can be attributed to a known or knowable source or process. NWD populations, then, are those in which there may be multiple, and often unknown, causative agents that create variability. Many of the datasets archaeologists work with are samples of objects or processes from very large populations. Taphonomic factors transform these datasets in unpredictable ways, and low-level behaviors of discard and disposal often obscure evidence of the higher-level social activities. Although attention to middle-range theory may identify factors that have transformed our populations, it is rarely the case these factors can be fully eliminated. Better attention to sampling may help to create more WD populations, but limitations on time and resources tend to work against this.

A WD variable is one that, through prior experience or through a body of theory, has proved useful in previous analyses. In some circumstances, a hypothesized variable may be at least initially considered to be WD, until it is shown through analysis not to be. Some sub-fields in archaeology, including archaeometry (especially compositional studies of ceramics or metals), and archaeozoology (with standardized methods for counting, such as minimum number of individuals [MNI] and number of identified specimens [NISP]), have developed robust WD variables. When combined with observations from ethnoarchaeology, middle-range theory, or findings from other disciplines that pertain to the research problem, our variables tend to be far more WD than our populations.

But it remains the case that few archaeological questions combine WD populations with WD variables, and this makes the use of more advanced quantitative methods problematic in many research contexts. During the heady days of the “new archaeology,” we borrowed methods from many disciplines and applied them with gusto to our research questions. Although these analyses were exciting, most of them were framed in poorly designed (or nonexistent) quantitative

idioms; in consequence we either misused the methods employed or came up with spurious or unlikely results. And, while similar abuses of methods can still be found in the literature, the discipline has become far more careful and explicit in the definition of quantitative idioms and in how these are created to explore social life in the past.

Statistics, mathematics, and disentangling social life

Statistics is a branch of mathematical reasoning that deals with the logic of inference under conditions of variability, uncertainty, and error. Classical frequentist statistical inference, that is, the approach to statistical analysis developed in the twentieth century by Sir Ronald Fisher, Karl Pearson, and many others, takes the form of testing hypotheses that are framed in statistical terms. A relationship between two (or more) variables is proposed, a test is performed, and the result is compared to the null hypothesis of no relationship between the variables. Here the *statistical* significance of a result is evaluated, but not its *importance* to a larger research question. If one rejects the null hypothesis of no relationship, this does not imply that the result is *scientifically* valid, since it is very likely that many competing hypotheses could be invoked to explain the lack of relationship between the variables. This does not mean that the statistical relationship of variables should not be tested, but rather that everything depends on how the research question is framed, on how the tests are employed, and, most importantly, on conducting the research within a robust quantitative idiom.

A recent paper by Kohler et al. (2017) is a good example of how statistics, mathematical models, and a well-conceived quantitative idiom was used to explore post-Neolithic wealth disparities between Eurasia, North America, and Mesoamerica. In the absence of written records, mortuary analysis, especially the counting of and comparison between objects placed in tombs or graves, has been a common approach employed by archaeologists to assess wealth in the past. Wealth, of course, is one way to determine relative status within a society, and status differences

are usually read as likely indicators of the presence of social hierarchies. Typically, multivariate statistical methods such as cluster analysis have been used to search for patterns in the content of tombs; and, on the basis of the outputs, hierarchies (or their absence) were then inferred. This approach suffers from numerous problems, both statistical and anthropological. Because there are few formal methods by which the results of a pattern-search method can be assessed, they were often subject to confirmation bias. And, from a behavioral perspective, it is not always clear that the materials that accompany the dead are necessarily direct indicators of their social status.

To overcome these problems, Kohler et al. (2017) built a robust quantitative idiom around the anthropologically sound concept of intergenerational wealth transfers and how that wealth is reflected in the household. They propose that hunting and gathering societies should have relatively little material wealth to transfer to the next generation, while societies based upon either horticulture or fully domesticated plants and animals have more material wealth than can be transmitted. To avoid problems with disposal behaviors and artifact preservation across these regions and to create a usable “object” that could compare ancient and contemporary households, through the use of ethnographic evidence and modern surveys, they created a proxy measure of household wealth: house size.

To compare households with this proxy measure, Kohler et al. (2017) used the Gini coefficient, a mathematical formula that measures income or wealth disparities and is extensively employed by economists to compare and contrast wealth disparities between nations. The value of the coefficient ranges between 0 and 1; values of 0 reflect perfect wealth equality, while values of 1 indicate maximal inequality. As expected, median values of the Gini coefficient tracked model predictions: hunters and gatherers, 0.17; horticulturalists, 0.27; agriculturalists, 0.35. What was not expected, however, was that post-Neolithic coefficients in the Old World tended to exceed those in the New World. To explain this difference, the authors turned to a series of statistical hypothesis tests of political scale (here identified as ranging from the family to the state) and of hemisphere in the sample used to calculate the Gini coefficients. They also tested political strategy against

hemisphere, and neither exhibited a statistically significant relationship. What does appear to be the causal variable in the hemispheric difference in wealth inequality is an “agricultural extensification,” as the authors called it, which was made possible in the Old World through the presence of domesticated draft animals that could be used for traction, secondary products, or consumption. Such species are not present in pre-contact New World sites. In effect, these animals created a basis for a dramatic increase in wealth for those who possessed them, and thus led to larger intergenerational transfers of that wealth. These patterns were revealed by a nonlinear regression of calendar years as measured by radiocarbon samples, tree-ring dates, or actual calendar dates (using the Gini coefficient). Displayed on the regression plot was the estimated date of the appearance of domesticated plants.

Although some may choose to question the ways in which houses were defined and sites selected for inclusion in the study and to debate the criteria used for defining political entities, the strength of this study resides in the careful integration of appropriate statistics, a well-understood mathematical model, and a robust quantitative idiom informed by anthropological theory. Using these tools, the authors have created an exemplary analysis of social life in the past.

Archaeological studies that employ models from human behavioral ecology (HBE) are excellent examples of the combined use of quantification and mathematics. Zeanah (2004), using a central place foraging (CPF) model, examined the sexual division of labor in the Late Holocene and in ethnohistoric periods among hunting and gathering societies in the Carson Desert of Nevada. Previous studies of these groups suggested a subsistence shift from a mobile, hunting-oriented strategy to a semisedentary gathering strategy, in response to diminishing densities of game. But, instead of looking at men’s and women’s activities jointly, as a means by which to predict site placement on the landscape, he contrasted women’s foraging goals with men’s hunting goals within a CPF model, in order to determine which (if either) was the optimal strategy.

Human behavioral ecology offers a number of distinct advantages for building a robust quantitative idiom. Its origins are in microeconomics,

it was subsequently translated into ecological science, and its advocates have developed a wide range of mathematical models that have utility in the analysis of making decisions about subsistence activities. Typically, HBE models have the following components: a goal (risk avoidance, maximization of energy return), a decision strategy (take a resource upon encounter or wait to explore a new patch), trade-offs (circumstances in which an alternative strategy might be more effective), recognition of constraints (what technologies are available), and, finally, a currency (a measure of costs of procurement, or time spent in a task). Quantification involves using the selected currency to calculate travel costs, the processing or handling times of specific resources, and search costs and to make estimates of the productivity of different resource choices—usually the caloric content of the species that could be exploited. The equations of the model are then employed to calculate, for example, return rates, which are used to infer an optimal diet within the context of the given constraints and goals. Zeanah's innovation here lies in examining women's and men's subsistence choices separately, which allows him to look at site-placement choices in a detailed manner and to suggest that, in this case, women's and human subsistence choices were not complementary but actually conflicting. This in turn suggests that the analysis of subsistence shifts in ancient settings needs to take the division of labor into account more seriously.

There are, of course, numerous objections to the application of HBE models to explore the social lives of past peoples. HBE models are based upon assumptions that are usually difficult or impossible to control. The environmental reconstructions upon which these models are based are often very coarse, and thus cost estimates may well be incorrect by orders of magnitude. Advocates of feminist perspectives on the past argue that defining the sexual division of labor in narrow terms promotes stereotypical thinking about women's lives. Although all of these problems are real, such critiques ignore the benefits of thinking about the past in quantitative or mathematical terms. Models have different utilities: some are conceptual, and their construction may promote clearer thinking about a process; some models are built to make specific predictions about a process, and others are built to explore a process

under different scenarios. These are significant advantages, and they provide an important alternative to the simple interpretive narratives of the past.

Multiscalar approaches to social life in the past

Archaeologists, following the lead of human geographers, have long been aware that social activities take place at multiple spatial levels within a society. Quantitative methods of all kinds—central place theory, distance-decay models, locational analysis, and many others—have been employed to define settlement hierarchies, trade relationships, activities within sites, and other social processes. The geographic information system (GIS) has become a standard analytic tool in the field, and spatial statistics of all kinds are embedded in the major software suites. R programming language, as well as Python and others, has been increasingly employed to look at spatial patterns in the archaeological record.

A common critique of these methods is that they define patterns without necessarily identifying causal factors that have led to their creation. Some theoretical perspectives, like entanglement theory, believe that relatively simple quantitative models of social and spatial processes are of little utility and are unable to capture complex anthropological processes. Even advocates of quantitative methods have expressed concern that these models have not lived up to their potential. A more likely explanation for the dissatisfaction with many of these models is that they were not created within a robust quantitative idiom.

Over the past decade, new quantitative and mathematical models have been developed to look at multiscale social phenomena of the past. One of the interesting outcomes of Kohler et al.'s (2017, 621) model of intergenerational wealth transfer was the observation that "wealth differentials are more strongly associated with increasing settlement size, regional population size and regional population density in the Old World than in the New World." They speculate that these scaling differences between the Old and the New World are based upon a more

intensive focus on economic specialization and long-distance trade in the former. The growth of cities and the attendant settlement hierarchies can be added as a possible causal factor. But a recent model developed by Haas et al. (2015) challenges the role these factors play in creating settlement hierarchies.

The settlement hierarchies of complex societies are described as “heavy-tailed,” which means that these societies are characterized by a large number of very small settlements and very few very large ones. This distribution can be formalized mathematically using a power-law function. This pattern is postulated to be driven by agriculture, warfare, and economic specialization, which lead to the development of central places. Haas et al. (2015) tested these assumptions using the settlement patterns of eight New World hunter-gathering populations in varied environmental contexts, and discovered that each of these settlement patterns is also heavy-tailed and could be described effectively by the power-law function. This surprising result indicates that incipient forms of settlement hierarchy could develop in mobile hunting and gathering societies and thus do not require more complex social formations for their development. Although a more complete explanation of the social processes that could account for this finding remains to be articulated, the authors suggest that “preferential attachment to previously occupied locations” may be operative (Haas et al. 2015, 15–9).

The quantitative idiom for this analysis is built around two variables that are reasonably well defined and have some ethnographic warrant: counts of diagnostic projectile points; and site area. The former signals person-hours of occupation, which means that lengthier occupations should result in the deposition of more points. Using temporal diagnostic points reduces the possible confounding effect of other uses of the site by groups using that space in different temporal periods. Site area reflects the size of the coresident group; larger groups tend to require more horizontal space. Should hunter-gatherer settlement systems follow the power-law model, we would expect both point-count and site-size estimates to reflect a power-law distribution.

These variables are not perfect measures of the size of the coresident group or of the dimensions of the site. The numbers of points at a site may

be underestimated by the combined effects of looting and taphonomic factors. Differences in surface collection strategies and the techniques used to define site area may also be problematic. Despite these potential sources of error, Haas et al. (2015, 7) argue that linear sources of error such as these would have little effect on the data and that, taken together, these error sources are well known to generate log-normal as opposed to power-law variation.

Social network analysis (SNA) has emerged as a powerful tool for exploring multiscale social processes. The method has origins in multiple disciplines, and archaeology has borrowed liberally from most of them. Very simply, SNA is based upon nodes and the connections between them. Nodes are simply the entities within the model, and in archaeology these are typically sites. Connections describe how nodes are linked to one another. Analyses of networks focus either upon the position and connectivity of nodes or upon the structure of the entire network. The mathematical foundations of network analysis come from graph theory, and a rich body of metrics has been developed to describe network structure and node characteristics.

SNA is remarkably compatible with many theoretical orientations in archaeology and has been used to explore an amazing variety of research questions in a diversity of regions, for example the diffusion of innovations, the flow of goods, interactions between Maya polities of the Classic period, exchange systems in foraging societies, and site placement in the Mediterranean. One of the great benefits of SNA is that it can be applied at multiple spatial scales, from the local to the pan-regional. This flexibility implies that SNA can be embedded in robust quantitative idioms; but, as in any mathematical model, the outputs of SNA must be interpreted within the idiom. The model-neutral metrics are of considerable importance as interpretative aids. SNA models also lend themselves very well to computational modeling and to other forms of computer simulation.

Mills et al. (2013) is a good example of an SNA embedded within a compelling quantitative idiom. The period from 1200 to 1450 AD in the American southwest was characterized by migrations, regional abandonments, and the appearance of larger villages and nucleated settlements. As the authors note, these patterns

were observed primarily at the level of the site or small region, and then extrapolated through comparisons of material culture across regions. Combining SNA, GIS, and an impressive database of archaeological ceramics representing a very large portion of the western American southwest, the authors discovered dramatic changes in network structure over the 250-year period under study. These included the eventual creation of two more or less separate networks, one operating in the south and the other in the north. Over time, both networks shrank in spatial scale until they essentially disappeared by 1450.

The quantitative idiom employed in this study was based on networks of decorated ceramics. Mills et al. (2013, 5785) postulate that the decorated ceramics were used in a variety of social contexts and may have served as markers of ideology or group identity. The anthropological processes that are thought to lead to similarities in ceramic assemblages at different spatial scales include local transmission of production, population migration, and the creation or maintenance of social boundaries. Frequencies of different ceramic wares, then, were the proxy measure for these social relationships. While the SNA does not permit an exact definition of the social process responsible for a relationship between sites on the basis of this proxy, it did create a context for the exploration of hypotheses about migrations and population aggregation that could be tested with other archaeological data.

Realist Philosophies of Science

GUY GIBBON

University of Minnesota, USA

Introduction

At its most general level, scientific realism is a view of the nature of reality and how that reality can be studied and understood. A basic assumption of the perspective is that there is a real world, both observable and unobservable, that different observers can independently experience through their naked eye, instrumentation, or theoretical modeling. The assumption of a completely objective reality is the underlying principle of science and is taken to explain the success of science. This entry reviews assumptions of scientific realism, challenges to it, and the status of scientific realism in the historical sciences.

Scientific realism: basic assumptions and their rationale

As a philosophy of science, scientific realism emerged in the middle of the twentieth century largely as a reaction to logical positivism, which encountered difficulties with its verification theory of meaning, analytic–synthetic distinction, distinction between observational and theoretical terms, and the theory ladenness of observation, among other problems (Liston 2017, 2–11; see **POSITIVISM**). Scientific realism became the leading philosophy of science following these debates.

Among the claims typical of scientific realism are the following, though not all scientific realists support all claims (Leplin 1984, 1–2):

- The best theories are at least partially true.
- The best theories do not employ central terms that are nonreferring expressions.

- To say that a theory is approximately true is sufficient explanation of the degree of its predictive success.
- The approximate truth of theory is the only explanation of its predictive success.
- Even if a theory employs expressions that do not have a reference, a scientific theory may be approximately true.
- Scientific theories are in a historical process of progress towards a true account of the physical world (so science makes progress).
- Scientific theories make genuine, existential claims.
- Theoretical claims of scientific theories should be read literally and are definitely either true or false.
- The degree of the predictive success of a theory is evidence of the referential success of its central terms.
- The goal of science is an account of the physical world that is literally true. Science has been successful because this is the goal that it has been making progress toward.

These claims have been grouped in scientific realism into three commitments. The semantic commitment supports the claim of a literal interpretation of scientific claims: Claims will be true or false depending on whether or not the entities in a theory exist and have been correctly described. The metaphysical commitment is a commitment to the claim that the mind-independent entities investigated by well-supported theories exist objectively. The epistemological commitment supports the claim that the entities in well-supported theories do exist. In review, the first and second commitments support claims that in a well-supported theory the entities in the theory do exist. The third commitment supports the notion that claims about the entities in a well-supported theory are true.

Arguments in favor of the claims of scientific realism have been advanced, often in reply to skeptical adversaries. Three are mentioned here.

Predictive success

A widely accepted observation of modern science is that many scientific theories are highly successful in predicting and explaining multiple phenomena, often with an extraordinary degree of accuracy. If scientific theories were figments of scientists' imagination and not anchored in reality, how can their predictive success be accounted for other than the base assumptions of scientific realism or a miracle?

The miracle argument

An implication of the argument above is that scientific realism is the only philosophy of science that does not make the success of science a miracle.

The corroboration argument

If entities do not exist as described in the assumptions of scientific realism, then the fact that different investigators using different modes of detection are able to identify the same entity would be another miracle, another astonishing coincidence.

Challenges to scientific realism and responses to those challenges

There have been many vigorous arguments against the claims of scientific realism. Four of the more common arguments in the philosophy of science literature are reviewed here, with brief replies by scientific realists. Arguments against strict realism from the perspective of perception theory and consciousness studies are then introduced.

The pessimistic induction argument

A common antiscientific realism argument points to the eventual failure of theories that were once considered empirically successful. This is true as well for successful theories whose unobservable terms are no longer thought to be existent. The pessimistic conclusion is that even well-supported theories today are not true or even approximately true either, and support

for a theory from a wide variety of empirical evidence is no guarantee that a theory is true or approximately true. Realists have replied that since replacement of one theory by a better one is a feature of the progress of science, it is to be expected that aspects of earlier theories will fail. This just proves the claim of the progress of science. In some instances, a theory may fail, but a well-supported concept or two, such as the concept of an atom, may be incorporated into a different theory in some form.

The social constructivist argument

This argument points out that during periods of scientific revolution, rapid change occurs in scientific knowledge. If scientific knowledge progresses through time at a regular rate, how are we to account for these sudden changes? Some social constructivists argue as well that new theories may only be a response to the appearance of new paradigms, paradigms that are incommensurable with older ones. Realists reply that the majority of scientists do research without considering whether their research is an example of one philosophy of science or another. For example, during the development of quantum mechanics in the 1920s, logical positivism was the dominant philosophy of science.

The underdetermination of theory by observable data argument

In some cases, the same observable empirical evidence supports several rival theories, but their unobservable data differ. These differences provide a skeptical argument against the truth of any of the theories. Realists have countered this argument by accepting the idea of underdetermination, for in their view theories remain only approximately true regardless of what evidence emerges, at least at the present. Over time, theory testing will get to the truth of the matter.

Skepticism about inference to the best explanation

In their research, scientists judge rival theories in part by deciding which hypothesis or set of hypotheses provide a better explanation of the

evidence than their rivals. But how is “better” determined? During times of scientific revolution and the emergence of new paradigms, what is considered “better” may shift. Scientific realists have replied that shared criteria like simplicity, consistency with other theories, and scope provide objective standards that aid this decision process. Scientific realists reply again that this is just part of the process of working toward a true theory.

A challenge to scientific realism not highlighted in the philosophy of science literature is our ability to sense correctly the world as it is. It seems there are physical limitations to how we access the world both in our sense organs and in our consciousness. Realists and people in general tend to take for granted the following five assumptions about our perception of reality: We are in immediate and direct contact with the world “out there” through our five senses; our information about the world is incredibly detailed and rich in information; we are capable of absorbing enormous amounts of information about the world quickly if not immediately through our senses; we all experience the same world; and the world exists “out there” independent of us. Perception theorists have challenged all of these assumptions (Epworth 2014). For example, the eye as one of these sense organs has structural limitations and other characteristics that limit and influence what we see and how we see it.

Likewise, our consciousness is not what we think it is. Among the conclusions neuroscientist Bruce Hood (2012) reached in his research are: “our brains use illusions to recreate the world. Everything is processed and abstract, with the brain putting in a large amount of effort to organize, interpret, and fill in missing information based on past experience,” and “our brain constructs models of the external world that provide a coherent story [of a complex reality] that enables us to interpret and predict what we should do next.”

Although we may use illusions to recreate the world, this is not always successful. Try eating rocks to save money on food, for example! According to Jaccard and Jacoby (2010, 7–10), “the obdurate character of our social and physical environment” will be a deciding factor in separating out useful and harmful interpretations of reality. In this view, scientific realism is about

the obdurate character of our social and physical environment.

There are also a variety of forms of what are called antirealism that provide alternative philosophies of science to that of scientific realism. Examples are empiricism, historicism, some feminist approaches, and various forms of pragmatism (Chakravartty 2007, 16–26).

Scientific realism in the historical sciences

While scientific realists are willing to accept the existence of observable and unobservable entities in physical sciences like experimental physics and chemistry, they generally deny that such realities exist in the social sciences and ignore historical sciences like paleobiology, paleontology, and archaeology. Because of this omission, the realism debate has been skewed in several ways (Turner 2007). By concentrating on experimental realism, the debate has favored emphasis on unobservables in experimental physics rather than in prehistory, deemphasized local underdetermination problems, which are more common in historical than in experimental sciences, emphasized novel predictive successes, which are rarer in the historical sciences, and ignored differences in the kinds of unobservables in these two different kinds of disciplines. All of this is likely another sign that historical sciences like archaeology are considered somehow less scientific than experimental physics or chemistry. Nonetheless, a mature, balanced overview of scientific realism will have to accommodate the gamut of the sciences, not just a select, favored few.

Science and Feminism

PENNY BICKLE

University of York, UK

Feminist archaeology has overturned how archaeologists think about and interpret sex and gender in the past and made a strong contribution to challenging the artificial division and opposition of “nature” and “culture.” It therefore has had a significant impact on how science is theorized in archaeology. The impact of feminism was felt later in archaeology than in cognate disciplines, or the philosophy of science, only gaining substantial mainstream attention by the late 1980s. At this time, two important appraisals were made of the subject’s androcentrism. The first critique demonstrated failings in how archaeology had written, or rather *not* written, about women in the past. Women had largely been ignored, casted as lacking agency, or past gender relations received little interrogation, ultimately reproducing and naturalizing modern experiences of female roles and status (Gero and Conkey 1991). The second critique focused on the role of women in the practice of archaeology, pointing to the restricted range and forms of work women were engaged in, and how this led to their marginalization in the political hierarchies and strategic positions in the work environment (Wylie 1997). Inspired by feminist theory, many archaeologists took on the “double challenge,” noted by Gero and Conkey (1991, 6), to both capture gender in the past and rethink conceptions of relations between women and men, producing a rich tradition of gender research in archaeology.

Archaeological sciences were not exempt from this movement. In a now classic example, Hastorf (1991) investigated paleobotanical remains and stable isotopes from human skeletons in combination with spatial analysis and ethnographic sources, to reexamine gendered food production and diet over the period during which Inca political influence was established in the Andes. The results demonstrated that men’s consumption

of maize increased more than women’s after the Inca conquest. Hastorf (1991) argued this was due to men’s greater involvement in feasts held by the Inca, as they sought to incorporate wider territories in their new political organizations by drawing on existing gift exchange practices. The study did much to demonstrate the importance of gender and household studies to answering questions about macrohistorical processes such as state-formation, but also emphasized the many ways in which social and cultural dynamics such as changing gender relations can intersect with research areas such as food production.

The feminist critique found a footing in archaeology in parallel to an important paradigm shift in Anglo-American archaeology. From the 1960s, “new archaeology” had sought to position archaeology as a scientific discipline, engaged in the task of determining and developing appropriate methodologies to test and produce laws of history, akin to those of the natural sciences. From the 1980s, postprocessual archaeology derived from postmodern thought sought to demonstrate that subjective social and political assumptions do influence the interpretation of archaeology: that data could not be understood as free from the cultural context in which the work was produced and written (Jones 2002). Debates between archaeologists advocating one of these positions could be vitriolic at times, but the issues raised by these contrasting approaches, that of the nature, extent, and possibilities of objectivity in research, had already been negotiated for some time by the philosophy of science and the feminist critique of science.

Feminists’ perspectives on objectivity in science have been characterized as highly polarized, stretching from arguing that it is only through the objective use of empirical data that value-free conclusions can really challenge the gender biases prevalent in society, to extreme relativism, in which science is thought to be so permeated by androcentrism, its knowledge should be entirely rejected (Wylie 1997). Wylie (1997) has argued that feminism’s commitment to making a real difference encourages researchers away from

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

DOI: 10.1002/9781119188230.saseas0522

supporting all-encompassing objectivism and extreme relativism, and, for the most part, feminist writing on scientific objectivity is notable for its call to find a pathway through both method and interpretation from multiple viewpoints, exposing the places where data and results are compromised by bias or culturally specific social values. By constantly assessing how scientific knowledge is being produced, who for, and the values by which it is judged as meaningful, feminism has sought to find space for different voices in science. For example, feminist scholar of science studies Donna Haraway (1988) has promoted a feminist version of objectivity, which she calls *situated knowledges* (what Wylie (1997) calls the view from “somewhere”), arguing that to do feminist science effectively, the practitioner must explicitly position themselves with respect to political and social debates of the contemporary world. Overwhelmingly, in among the variety of approaches, this has been the message from feminist philosophers of science; that knowledge is always contested and partial, that systemic bias is capable of permeating the questions science asks, its methodologies, and empirical results, but that this situation can be effectively challenged from a plurality of perspectives to promote what are ultimately more rigorous and productive understandings of the (contemporary) world.

Writing in 1997, Conkey and Gero summarized what they saw as the four significant points archaeology had adopted from feminist philosophy of science. (1) The role political contexts continue to have in defining who produces knowledge and the way it is assessed is undeniable. For example, the concepts such as “man the hunter” and “women the gatherer” have been repeatedly shown to be based on lazy stereotyping, but continually to be frequently reproduced both in text and visualizations of prehistory. (2) True objectivity is unachievable, and claims that conclusions are based on it are likely to be unreliable. Multiple routes to historical insight are now taken, with the confident use of fiction and discussion of emotion to expand the repertoire of archaeological inferences. (3) Challenging binary thinking and taking ambiguity in data as meaningful has often been achieved through “intimate knowledge,” such as that of Spector’s (1993) account of life at a Wahpeton Dakota

village, starting from close description of an awl as entry point into exploring daily life and gender roles. (4) There is a commitment to challenging the current conventions, by increasing the variety of voices heard in archaeology.

From the late 1990s, third-wave feminism shifted the lens from gender *sensu stricto* to constructions of identity and the body more broadly, analyzing the intersections between age, gender, sex, class, sexuality, kinship, and ethnicity. A pioneering example of this approach can be seen in Meskell’s (1999) investigation of ancient Egyptian social life at the Deir el Medina cemetery, illustrating the participation of material culture in the performance and negotiation of Egyptian attitudes to corporeality and personhood, mediated through different aspects of identity such as age and status. The archaeological sciences have made a strong contribution to identity studies, often through techniques focused on the human skeleton (such as isotope studies on diet and mobility) and paleopathology and osteological techniques on disease and habitual activity (see OSTEOLOGY and PALEOPATHOLOGY), particularly in illustrating the variation across populations and recovering the history of those who may be materially less visible in the archaeological record (i.e., buried without grave goods). This analysis can be presented with little explicit reference to feminism, signaling perhaps that many of the key points stressed by feminist archaeologists have by now been adopted by the discipline.

Such optimism is not shared by everyone, as evidenced in the 2013 special addition of the journal *Current Swedish Archaeology* on archaeological science in archaeology. Papers in the volume repeatedly highlight tendencies in the interpretation of data produced by the natural sciences toward essentialization (e.g., the categories of male and female are defined by unchanging characteristics), especially when social identity is inferred directly from biological markers. In this respect, the use of DNA and ancient DNA (see GENETICS: ANCIENT) to answer questions of population spread, migration, and origins has been particularly controversial. The ability of genetics to reveal biological sex and genealogy will undoubtedly contribute hugely to the future of archaeology, but how historical significance is understood from the data requires both the critical appraisal of how the

data informs on specific archaeological questions and subsequent reevaluation of existing models or hypotheses. As Wylie (1997) argues, despite extensive debates about archaeological method, the means by which conclusions are drawn in archaeology is often by moving repeatedly between background knowledge and theories, and the evidence, to create chains of inference. Irrespective of where individuals stand on both science in archaeology and feminist approaches, this now characterizes archaeological method, with researchers pursuing a variety of perspectives in relation to objectivity versus social constructivism.

Despite the substantial literature reflecting on and championing the feminist perspective on science outside the discipline, and separately receiving discussion and making undeniable contributions to the development of archaeology, explicit considerations of the impact of feminism on *archaeological science* have faded since the first rush of papers in the 1980s and 1990s. Although ideas from key feminist thinkers such as Haraway (1988) and Wylie (1997) have been drawn upon (e.g., Jones 2002), claims to an explicit feminist standpoint in the archaeological sciences more recently have been minimal. While the varied feminist critiques have largely focused on the archaeological discipline as a whole, multiple positions are taken up by archaeologists with respect to science, ranging from the unambiguous classification of archaeology as a natural science, to suspicion, and this appears to have resulted in feminist perspectives being lost in among debates about the relationship between archaeological theory and archaeological science.

This does not mean, however, that recent developments in feminist theory more broadly have not been felt in archaeological practice. The “material turn” in archaeology, and the humanities more widely (see SUBSTANCES AND MATERIALS), has involved a critique of anthropocentrism often drawing on the feminist skepticism that a universal “human” perspective can be carved out separately from the material, animal, and ecological world (Fredengren 2013). Under various guises, such as symmetrical archaeology (see SYMMETRICAL ARCHAEOLOGY), these approaches have argued that the division between “objective” science and “constructivist” humanities was another example of the kinds of binary thought

feminism had criticized. Rather, ontological accounts are now increasingly favored, focusing on what the world “is,” in place of the previous debates between processual and postprocessual archaeologies about how best to “know” the world. The first steps towards archaeologies inspired by this approach have largely focused on “things” and materials, and tend to favor drawing on a wide variety of data, including that of archaeological science. For example, Fredengren (2013) discussed how past bodies can be investigated as assemblages drawing on data from isotopes and DNA, pointing to how recent DNA analysis of dental calculus reveals changing assemblages of humans and bacteria over shifts in diet. Future research will no doubt bring more examples in this vein.

Within archaeology, the concepts of “science” and “feminism” are at once both sets of analytical practices and critiques on the discipline itself. Many of the conflicts and objections around both the use of science and the feminist perspective in archaeology have arisen when these concepts have been considered as mutually exclusive products of archaeological research. Recently, it has been recognized that they are, rather, practices that better inform research, and as such these concepts have been used to find more fertile ground for interrogating the past, and become more readily combined.

Science and Politics

KOJI MIZOGUCHI

Kyushu University, Japan

“Science,” in common understanding, is defined thus: “knowledge or a system of knowledge covering general truths or the operation of general laws especially as obtained and tested through scientific method” (Merriam-Webster dictionary: <https://www.merriam-webster.com/dictionary/science>), with the scientific method defined thus: “principles and procedures for the systematic pursuit of knowledge involving the recognition and formulation of a problem, the collection of data through observation and experiment, and the formulation and testing of hypotheses” (Merriam-Webster dictionary: <https://www.merriam-webster.com/dictionary/scientific%20method>). Truth is commonly identified as the observable state of occurrence of *things* (that constitute the world) that are recognized as they are by everyone, anywhere, at any time. When it comes to *material things*, their state of being can be observed, described, and shared, so long as a certain rule or framework is established and adopted, and a certain equipment is deployed. Exposing a material thing to a certain condition transforms it from a certain state to another in a certain manner, regardless of who does it, when it is done, and where it is done. In other words, secure forms of *causality* and *repeatability* exist, which can be established if we *systematically* handle material things by formulating hypotheses and testing them through observation and experimentation. *Indeterminacy* in the specification of causality cannot ultimately be overcome because of the inevitable intervention of the mechanical–technological limit of resolution and of observation; and the philosophy of science dedicates considerable effort to solving various issues concerning how to deal with indeterminacy, how to secure repeatability, and to what extent this can be achieved. When it comes to dealing with *human beings*, also things

constituting the world and an important subject of scientific endeavor, however, we must confront a fundamentally different set of issues; for the consideration of issues concerning science and politics, we must deal with human beings as a subject of science, as the practitioner of science, and as the recipient of the outcomes of scientific endeavor.

Material beings have neither consciousness nor memory, and do not change their behavior individually or collectively in reaction to changes to their environment/effects from the outside. Human beings have consciousness, memory, and language, and other means to communicate their thoughts; they change their behavior individually and collectively in reaction to changes to their environment and to effects from the outside. They also have the ability to choose not to react to them. The fundamental and constitutive characteristics of the former are the foundation of the repeatability of cause–effect relationships. That of the latter, however, mean that cause–effect relationships are not always repeatable, in that human beings might change the way they react to a certain condition by referring to what happened previously under similar circumstances. They can also change the way they react to a certain condition by referring to what they know happened elsewhere under comparable circumstances. Most often, the society of which a person has acquired knowledge is their own one; this being the case, they can change the way that they act by referring to what they have learned, and such change effectively changes the society of which s/he is a member.

This endless feedback loop, conceptualized by Anthony Giddens as the double hermeneutical nature of social sciences (Giddens 1984, 284), is exactly the point where science has intrinsic and inevitable linkage with politics. The methods of science constitute sets of tools, skills, logics, and ways of thought, and attitudes as well as subject matters; each of them forms a unique mode of existence which can be characterized as a “habitus” (Bourdieu 1990). A habitus, or an embodied way of how to get on

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

© 2018 John Wiley & Sons, Inc. Published 2018 by John Wiley & Sons, Inc.

DOI: 10.1002/9781119188230.saseas0523

with the object and subject world, consists of a certain set of knowledges and values; these are internalized through the recursive enactment of a certain set of practices on, by using, and mediated by a certain set of items/resources, material, virtual, symbolic, or otherwise. Such a set reflects/is constituted by the mode in which those items/resources are distributed across the social landscape in which scientific practices are embedded and conducted, and such items/resources are *unevenly distributed*. Negotiations over the ways in which different resources are allocated to different social groups take place all the time at each and every social context, including laboratories, research facilities, and excavations. If we categorize such negotiations as political practices, virtually every moment of our daily lives, including our scientific practices, is political. Furthermore, the uneven distribution of various types of resources and capitals, including both economic and cultural-symbolic, is engineered by those who are dominant in each unit of social integration, ranging from such microunits as a laboratory and an excavation through a globalized sociopolitical/economic sphere, and resistances are organized by the subordinate. Scientific revolutions, conceptualized by Thomas Kuhn as “paradigm shifts” (Kuhn 1962), are caused by not only the accumulation of knowledge, inventions, and technological developments but also those human factors involving the reproduction and transformation of power relations, which can only be characterized as political.

This can be seen most characteristically in the context of colonial archaeological practices. Against the background of the “diffusionist” paradigm—which explains sociocultural changes as the result of migrations and/or the spread of sociocultural traits—complex societies with variously developed social hierarchies in colonized areas, most prominently exemplified in the famous case of the site of Great Zimbabwe, were interpreted as having been constructed by migrant populations originally from the core regions of the pristine ancient civilizations or their vicinity. The achievements of these civilizations are acknowledged, since modern European societies are identified as their inheritors. Various kinds of pseudoscientific practices, including intentionally arbitrary

readings of ancient literature/chronicles and, again, intentionally arbitrary comparisons of specific attributes of indigenous artifacts with those of the aforementioned “civilized” areas, serve to demonstrate the existence of direct connections that resulted from migrations from the pristine ancient civilization areas and their vicinities to the colonies.

The “diffusionist” paradigm itself was organically embedded in the socio-political/cultural/economic conditions of the nineteenth and early twentieth centuries, when competition between the nation states of Europe and elsewhere over territories, resources, and markets generated the condition in which the allocation of aforementioned resources was engineered by the state authorities for political purposes; this included the tight integration of the inhabitants of a state as a distinct ethno-national group with a shared history (of enduring hardship) and destiny. The newly developed middle class/educated elite, including practitioners of newly disciplined scientific disciplines, played a fundamental role in the (re-)invention of ethno-national traditions, and when it comes to colonial interventions, the outcomes of their scientific endeavor legitimized colonizations as enlightening endeavors. It has to be noted that the sense of legitimacy and duty driving the elite at the time was significantly based upon belief in the absolute supremacy of empirical sciences over folk/indigenous knowledges; the political habitus, so to speak, based upon this empirical science-based habitus, made the aforementioned pseudo-scientific practices legitimate and natural, despite that the latter fundamentally betrayed the principles of empirical science.

Let us continue tracing the historical transformation of the relationship between archaeological practices and contemporary society. By dismissing the “diffusionist” paradigm as the “aquatic view of culture” (Binford 1965, 204), the so-called processual paradigm emerged in the 1960s. This paradigm was based upon the belief that archaeological knowledge production was a scientific endeavor in the sense that the traces of human thoughts and deeds could be treated in the same manner as material things. Alternatively, some would claim that the “paradigm” tried, and still is trying, to limit its scope to the elements of human thoughts and deeds that showed

material thing-like patterns. In this framework, the archaeologically retrievable traces of human thoughts and deeds were examined in terms of their co-variation with traces of the factors that could be inferred to constitute the *environment* of such thoughts and deeds, and their *transformation* was explained in *functionalistic* terms—that is, the transformation of patterned thoughts and deeds for the regaining of the stability of the social whole. It was intended to minimize any involvement of subjectivity, a theoretical premise directed by logical positivist versions of the philosophy of science (see POSITIVISM), as well as Karl Popper's injunction to secure the falsifiability of statements (see EMPIRICISM). This reliance upon positivist philosophy exemplifies the habitus shared by many sectors of archaeological communities across the developed world at the time, which was organically connected to the sociopolitical climate of the era. This was the Cold War equilibrium based upon the balance of military power between the United States, the USSR, and their respective allies, which made social phenomena the subject of engineering based upon functionalist input-output modeling. Moreover, input-output modeling-based research projects were directed toward the generation of clear and coherent results, which proved successful in attracting research funding. Furthermore, the Cold War equilibrium prevented rising colonial and post-colonial tensions from surfacing to cause significant impacts upon the policy frameworks of the United States, the USSR, and their allied nations, particularly if they might jeopardize the implementation of the policies concerned. Those conditions enabled the dominant habitus embedded in the archaeological practice of the time to identify and constitute archaeology as a search for law-like generalizations, a discipline modeled on the natural sciences.

The end of the Cold War (in the form of the collapse of the USSR and its allied sociopolitical, economic, and cultural block) in the early 1990s accelerated the process in which first economic, and then sociocultural and political globalization led to the deepening of post-colonial tensions, and their surfacing to the extent that they began to have significant impacts upon international politics, which had begun well before the end of the Cold War. This, together with

other consequences of globalization, prominently including the re-perpetuation of center and periphery relation-based asymmetry in access to capital and resources, has led to the rise of the fundamental critique of modern science as a habitus perpetuating the western domination over their former colonies by prioritizing the Cartesian view/model of the order of the world. At the same time, the rise of the *internal critique* of the scientific community has led to the increasing realization of *indeterminacy* in scientific knowledge production and *causation*. Those trends have come together and resulted in the opening up of the critical discursive space of the history and philosophy of science in which the involvement of *historical contingency* and indeterminacy in scientific knowledge production is linked to the relation of dominance that exists between the producer and consumer, between the imposer and the recipient, and between the observer and the observed among those who are involved and/or implicated in scientific knowledge production.

In archaeology, this realization initially took the form of the emergence of so-called post-processual archaeologies, which emphasized the value-ladenness of archaeological knowledge production, the importance of promoting multivocality within it, and the intrinsic and inevitable linkage between politics and archaeological knowledge production. In the early phase of the postprocessual "movement," the relationship between those who advocated the search for law-like generalities in the traces of past human lives as well as past human lives themselves and those who emphasize historical contingency in the patterning of human practices and the importance of the conscious, strategic use of material culture was a hostile one. However, it is presently increasingly common to combine these views and approaches by selectively adopting their theoretical and methodological components in individual research paradigms and projects. This not only shows the maturity of archaeology, which some would describe as the emergence of multiple "archaeologies," but also is a reaction to an increasingly complex world containing increasingly polarized value systems and world views. Such a condition requires a highly nuanced treatment of the subject of one's research and a highly strategic choice of subject

matter, and of the manner of presenting the outcome.

It has to be noted that presently a new and somewhat problematic trend is emerging: The rapidly increasing popularity of the application of natural scientific tools such as strontium and other isotope analyses and ancient DNA analyses is resulting in an uncritical readoption of diffusionist modes of explanation for social transformations, and the restriction of the subject matter of archaeological investigation to what can be simulated in the form of cause–effect linkages. This trend can be seen as a way of reacting to the increasing complexity of the world and the polarization of values and world views by confining one’s research interests to what can be simply and (apparently) comprehensively described and/or explained. The development and elaboration of tools and means with which to pinpoint the place of origin of an archaeological material, whether it be an artifact or a skeletal individual, are undoubtedly of value. However, if they unwittingly encourage an attitude of uncritically connecting the outcome of such application of natural scientific tools to archaeological inferences generated by archaeological paradigms that have long been rejected owing to their harmful political implications (such as discrimination or the dismissal of indigenous world views fostered by colonialism), we will need to adopt a cautious and critical approach to them.

In conclusion, it needs be emphasized that all scientific practices embody political elements in their performance as much as their outcomes, and that any scientific practice that concerns itself with human thoughts and deeds is inseparable from relations of dominance. In order to practice archaeology (or archaeologies)

in a socially responsible manner, we have to fully understand the enabling, constraining, and risk-generating elements and characteristics of science, as well as to recognize exactly in which domains we can seek law-like generalities and in which we have to be aware of, and focus on, historical contingencies and indeterminacy. All those points can only be fully appreciated if we accept the fact that the conduct of science is a political act.

Scientific Practice

PATRICK ROBERTS, JESSICA HENDY, and
NICOLE BOIVIN

History, Germany

Introduction

The concept of “scientific practice” in relation to archaeology has varied both geographically and temporally. Even today, varying opinions exist as to what this term actually encompasses. Some will see all of archaeology as “scientific practice,” with trenches, surveys, and typological study of past material culture being “experiments” and yielding new facts and information. To others, “scientific practice” has little role in a humanities subject that studies multiple “truths” and has few means of empirically validating theories. However, perhaps the most common current understanding of “scientific practice,” given the huge diversity of biomolecular, archaeometric, and chronological methodologies that are now available to archaeologists, frames archaeological science as a subdiscipline, and just one part of an approach to the study of the past. In line with this, here we take “scientific practice” to mean the application of laboratory-based scientific methods, often imported and adapted from diverse fields in the natural sciences, in order to produce empirical data that can be used to test well-formulated questions.

Yet while this definition may suggest a simple categorization of “scientific practice” within archaeology, we note that this is misleading. Latour (1987, 1993), among others, has argued that all science is inseparable from its social, political, and economic context, and this is particularly true for archaeological science. “Scientific practice” in archaeology involves collaborative negotiation between curators, excavators, numerous different scientific specialists, governments, landowners, and, in a “world archaeology,” diverse national archaeologies,

Indigenous groups, and other stakeholders. Moreover, archaeological science is accountable to the public tax-payer, policy-makers, and politicians (often across national boundaries), and funding bodies operating on increasingly constrained budgets. In this entry, we address the issues arising from these diverse relationships and attempt to recommend an actionable, and ethical, pathway for “scientific practice,” from the collection of samples to the presentation of findings to archaeological collaborators, funding providers, and, ultimately, the broader public.

Do we really need “experts?”

“Scientific practice” in archaeology is today linked to a growing specialization of researchers within the discipline, not only in the academic sphere but also within commercial archaeological units. This is not a new phenomenon, and archaeobotanists, archaeozoologists, and geoarchaeologists have been regular members of excavation and archaeological departments for a number of decades. However, the proliferation of new methods, including ancient DNA analysis, proteomics, remote-sensing, and a range of new chronometric and mass spectrometry-based methods (from optically stimulated luminescence dating to inductively coupled plasma mass spectrometry), among others, has meant that the number of potential specialisms is greatly increasing. Moreover, whereas archaeobotany and archaeozoology have frequently been utilized by those who would describe themselves as “archaeologists,” investigating a particular temporal and geographical question (e.g., Fuller et al. 2011), the practical knowledge required by newer applied sciences, especially if they are to meet the rigorous standards set by the parent disciplines, has often led to a separation between excavators and curators, on the one hand, and the specialists with whom they collaborate, on the other.

This division leads to issues on both sides. Methodological specialists often validate their results on the basis of statistical, biological,

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

DOI: 10.1002/9781119188230.saseas0524

chemical, or biogeochemical parameters inherited from the application of their methods in the natural or earth sciences. In these parent disciplines, experimental designs can be constructed to control the number of variables, or biological or technical replicates can be implemented in order to add statistical weight to generated findings. Applied to archaeological contexts, however, such approaches may fail to consider issues of taphonomy, preservation, sample scarcity, context, and chronology, which often remain unexplored by methodological specialists. For example, although measurements of ancient DNA, fatty acid residues, or bone collagen may well meet appropriate scientific quality controls, very different conclusions will be reached depending on what is understood regarding their date or cultural context. Additionally, excavators and curators are often left wondering why specialist methodological papers, that seemingly ignore long-held arguments and knowledge in archaeology, are successfully published in high-impact journals. Finally, on a practical basis, specialists can fail to take into account cultural, political, national, post-colonial, and other tensions involved in the sampling and export of sensitive material culture and human remains in their laboratories or the field.

Similar risk to scientific practice comes when excavators and curators are content to simply send off samples to a scientific “black box,” located in a different department or country, without making adequate attempt to understand the potential methodological pitfalls involved in specialist studies. This can lead to the idolization of “data” as *de facto* support for existing theoretical and political biases. This means that innovative methods and data can fall into circular traps where biased research design leads to biased findings, doing little to advance archaeological knowledge. Excavators and curators also risk making decisions on the curation and provision of material that can hinder scientific advancement. This includes the facilitation of a method that may obliterate material that could have been utilized by another perhaps superior method, and the provision of sample sizes that are too small to provide effective results, leading to doubt in the method and the needless destruction of samples. Alternatively, seeing the vast growth and refinement of archaeological science techniques,

they may be reluctant to provision samples to researchers in the hope that a better approach may be just around the corner, an attitude which in itself may hinder methodological advancement. As such, a key challenge in scientific practice is to address how, and to what extent, divided “experts” in archaeology and archaeological science can fruitfully combine to produce truly novel understandings of the past.

Archaeological science in a world of “alternative facts”

“Scientific practice” does not just involve relationships between excavators, curators, and methodological specialists, however. Archaeology as a discipline is increasingly judged on the relevance of its research output to political agendas, economic development (e.g., tourism), and its interest to the general public. This instantly places pressure on researchers, especially in regions, countries, or institutions with limited funding, to make their projects and results more attractive to these interest groups. As a result, at least in part, archaeological science is forced to move beyond a straightforward position of experimental verification and fact-making, and address what happens to their data and arguments in the “hands of others” (Latour 1987), such as the media and politicians.

At a time when the public in many regions of the world seems increasingly willing or susceptible to accepting “facts” conveyed by politicians, media outlets, or interest groups, often with little regard for verification, the “hands of others” are increasingly prominent in archaeological scientific practice. On a political level, and notably still relevant today, Latour discussed 20 years ago how climate change policies in the United States, and the scientific information used to support them, change swiftly between alternating Republican and Democratic administrations (Latour 1993). Archaeology’s growing interest in the past impacts of climate change and anthropogenic alterations by human societies through time may not fit with the views of the governments or private sector organizations that support research, with implications for funding and research orientation. Similarly, while

archaeological applicants to the National Science Foundation are judged primarily on how their research can benefit America, with titles often individually ridiculed among the House of Representatives (Mervis 2014), archaeological applicants to the Deutsche Forschungsgemeinschaft in Germany are encouraged to take a “global” approach. Such examples demonstrate the contrasting present-day political outlooks of these nations and the effect they can have on scientific funding and practice.

In a broader sense, funding bodies and political groups, with limited funds to distribute, can often favor individuals and projects with a “story” that can be sold to the public and news outlets and thus justify expenditure. It is far easier to do this with broad-sweeping statements, that overstate the realistic contribution of the produced data, than it is with specific, more critically interpreted studies. However, such research has the potential to damage scientific credibility, at least in the presentation of the resulting data. Moreover, it is much less likely that a funding body will support basic methodological developments when compared to the application of methods to a period or region of public interest. Such propensities can hinder the discovery of methodological pitfalls, and prohibit the refinement of archaeological science techniques.

A recent prominent example of archaeological science being drawn into “story-telling” can be seen in the attention surrounding the discovery in the United Kingdom in 2012 of a skeleton suggested to be that of Richard III, former King of England. While the contextual, genetic, and forensic evidence for this identification is no doubt strong, the interpretive caution often expressed by archaeological scientists was in some part swiftly lost in the production of a narrative played out by news outlets and the wider public (King et al. 2014; Lamb et al. 2014). Similarly, in playing to a public and media fascinated by “firsts,” recent archaeological science has at times devoted inordinate resources to the recovery and analysis of finds suggested to be the earliest in some particular category, regardless of the sometimes dubious significance and scientific merit of such achievements.

Archaeological science in action

Scientific practice in archaeology is thus enmeshed within the social, political, and economic context in which it unfolds. Science is not a separate, “pure” sphere in which the practice of “data” production is disconnected from the rest of society. Instead, interpretations, conclusions, and project proposals will be influenced by individual archaeological and museum collaborators, institutional and political administrations, and funding bodies. So how can we put robust archaeological science approaches into action? Essentially, we must understand the interest groups involved at every stage in the handling of scientific practice, recognize these potential biases, and provide workable and transparent criteria by which to evaluate and interrogate results.

Successful integration of archaeological and methodological expertise is aided by the bringing together of these two types of specialties within individual projects, departments, and institutions. On a more individual basis, success is also aided by the initiative of nonspecialists striving to be genuinely involved and engaged with the process of applying scientific methods to research material they provide to specialists, including grappling with the method’s potential pitfalls and challenges. Finally, scientific specialists should provide clear and transparent guidelines to educate potential users about their methods so that everyone can be involved in validating the scientific process. One good example of this is the recent release of “Organic Residue Analysis and Archaeology” by Historic England (2017), in combination with specialists across the United Kingdom.

Within this perspective it is also important that projects with an archaeological science dimension are developed collaboratively, with excavators, curators, and methodological specialists all being involved at an early stage wherever possible. Sampling and curation of material should be performed with a dialogue between the institution at which it is stored, previous researchers who have utilized the same material, and cultural and political interest groups where relevant. The placement of new methodologies in an accessible format, such as on websites (e.g., University of York 2016), with attached videos and sampling guides,

allows excavators, local collaborators, and curators to actively seek collaboration and understand how new methods can benefit their collections, balancing out the currently common practice in which the impetus for collection sampling comes from methodological specialists and their independently developed research agendas. In some cases it may even be that these individuals can undertake the sampling themselves, with specialist guidance, placing them at the center of the process of data production from the very beginning.

In the wider political and economic sphere, it remains a reality that funding and research publicity will be shaped by political and economic agendas. Where possible, as with scientists across other disciplines, it is important to publicize the realistic positives and negatives of any given approach, both within the academic sphere and to the international public. While this is a hard thing to action given that academic careers depend on securing funding and generating successful outcomes, this can be helped by ongoing discourse among archaeologists and methodological specialists, and indeed journalists, regarding what is possible and what is not. Publication of “replies” to high-impact papers that have overstretched their mark, the development of criteria by which reviewers and journalists should question spurious interpretations, and the emphasis on methodological development where funding is not such a constraint are potential avenues through which to achieve this.

Scientific practice in archaeology is an area of exciting potential and notable challenges, significantly enmeshed with current social, political, and economic agendas and dialogues. Ethical and effective scientific practice demands engagement by both scientific specialists and archaeological researchers responsible for excavation and artifact curation. Engaging in scientific practice does not mean permission to overlook archaeological responsibilities in pursuit of an untethered and objective natural sciences approach. As scientific practice in archaeology grows and diversifies, the discipline’s commitment to a broader anthropological agenda that prioritizes diversity, responsibility, and engagement with both mainstream and marginalized interest groups should remain a key priority.

Scientific Revolutions

STEPHANIE KOERNER

University of Liverpool, UK

Efforts to rethink problematic generalizations about a supposedly singular (*the*) Scientific Revolution may figure among the most important ways in which characterizations of the arts and the sciences as opposed and mutually incompatible “two cultures” are being called into question today. The publication of Thomas Kuhn’s *The Structure of Scientific Revolutions* ([1962] 1970)—and cross-disciplinary discussions of the issues it raises—marked turning points in this development; and in the emergence of numerous novel interdisciplinary trading zones between the arts, humanities, and material and life sciences, evidenced throughout this *Encyclopedia*. Many aspects of Kuhn’s work have parallels in earlier and contemporary scholars. Many aspects of Kuhn’s work had predecessors and parallels in the work of some of his contemporaries. However, it was most remarkable in its original contexts, and remains valuable to revisit for a variety of reasons, including the contributions that it made to appreciating the importance of contextual approaches to rethinking “scientific revolutions” (including those happening today).

In order to contextualize this entry, it bears underscoring that it was not until the emergence and spread of remarkable interest in the cross-disciplinary significance of issues raised by contrasts between logical positivist and logical empiricist philosophies of science, and Kuhn’s “new philosophy of science” (or history and philosophy of science), that philosophy of science became a key area of archaeological specialization; and archaeology became a key area of specialization in the history and philosophy of science (see, for instance, PHILOSOPHY OF SCIENCE). Issues that Kuhn’s conception of “scientific

revolutions” raises have become important trading zones: for instance, within fields as a model of disciplinary history (e.g., archaeology); between fields (e.g., the History of the Philosophy of Science (HPS), science technology studies, culture studies); and as new fields in their own right (e.g., historical epistemology).

All this underscores the huge range of the intellectual and social contexts of the topic of “scientific revolutions,” and motivates our focus here on: key dimensions of the topic of philosophical implications of “scientific revolutions;” change in approaches (relating to Kuhn’s work) to “scientific revolutions” as a paradigm for archaeology’s disciplinary historiography, and to insights that the notion of a singular (*the*) Scientific Revolution calls for continual rethinking; and the dynamics of current foci and future directions of work, relating to archaeology’s bearing upon challenges of rethinking incommensurability and taking the arts and sciences equally seriously.

“Scientific Revolutions” in long-term historical perspectives

According to Copernicus (1473–1543), the concept of a “revolution” (a term for a form of movement) becomes a key principle in the sun-centered model he put forward as an alternative to predominant Ptolemy (100–168 CE) and Aristotle (385–323 BCE) based scholastic models of the earth-centered structure, composition, and forces of the world. It is not likely that a conception of the philosophical significance of such changes developed until the end of the Enlightenment, especially, in the work of Immanuel Kant. Kant’s *Critique of Pure Reason* ([1781] 1999) and *Critique of the Faculty of Judgment* ([1780] 1955) stressed the philosophical significance of the “Copernican Revolution,” and described it as a revolution in “world view” or “mode

of thought”—with direct bearing upon such complex philosophical questions as those about the dynamics of humanly constructed “phenomena” and “things in themselves;” about how humans attribute meaning to experience; and about the ethical significance of human capacities to treat one another as “ends in themselves” rather than “means to ends.” This range of ideas has indubitably contributed to the interest in and the liveliness of debates about Kuhn’s conceptions of “the structure of scientific revolutions” and “paradigm incommensurability.”

The eighteenth and nineteenth centuries saw science become an historical study area, and the emergence of polemic over continuity (gradual) and discontinuity (punctuated) models. Discontinuity models went out of favor for a variety of reasons, including implications for foregrounding conflict. Continuity models marginalized conflict, and conformed to positivist philosophies’ characterization of the history of science as a gradual cumulative process whereby errors are corrected and theories move towards supposedly timeless truth. All this was called into question by Alexander Koyré, who figures centrally among twentieth-century critics of such positivist arguments, as that historical facts somehow “speak for themselves.” Koyré is widely recognized as the scholar who coined the concept of the “scientific revolution” (Kuhn [1962]1970). Koyré (1965) characterized this revolution in terms of the undermining of traditional cosmologies; and the emergence of a geometrical picture of the universe; traditional earth-centered celestial and sublunary spheres were replaced by a universe in which geometry united astronomy and physics. In Koyré—as in Kuhn—these processes are not at all characterized in terms of notions of a supposed replacement of so-called irrational by more rational modes of thought. Koyré stressed how the spread of beliefs in the authority of mechanical natural philosophy and experimental science became linked to highly problematic images of individual psychology and society based on interpretations of Newton’s *Principia Mathematica* (1687) and John Locke’s (1632–1704) *Essay on Human Understanding*. Central motifs in these images included “an atomic” psychology and sociology that reduced human life ways and societies to individual and clusters of atoms attracting and repelling one another.

Change in approaches: three examples

Kuhn’s work in context

For many working in the humanities and social sciences during the 1960s through the 1990s, it may have been difficult to imagine an era when their area of disciplinary specialization had not been characterized as experiencing “crises over representation” and deep and far-reaching “paradigm change”—comparable at some level with what Kuhn described in *The Structure of Scientific Revolutions* ([1962] 1970). The second half of the twentieth century saw discipline after discipline split its goals along axes of such dichotomies as those of art–science–nature–culture, and materiality versus the meaningful. Debates over archaeological methods and theory parted ways around processual and post-processual responses to such processes as those of David Clarke (1973), who characterized it as the field’s “loss of innocence” and “critical self-conscious phase.” Much disagreement revolved around archaeology’s classification as a “human science” or a “natural science” (Preucel 1991, 17).

Polemic over such vexed options did not develop in a vacuum. The twentieth-century history of the arts and sciences has often been seen as marked by two “crises over representation.” One centered on knowledge concerning “nature,” and was marked by crises over clashes between positivist philosophy and Einstein’s Relativity Theory. The other centered on knowledge concerning “culture,” and was marked by crises over clashes between positivist claims about value-neutrality and the extent to which deeply value-laden problematic interpretations of history and cultural diversity were linked to “colonialist,” “nationalist,” and “imperialist” ideologies. Relativity Theory went against the grain of Newton’s “laws of matter and motion” and positivist presuppositions about a unified hierarchical system of sciences, grounded in the objectivity of “primary”—quantitative versus the subjectivity of “secondary”—qualitative data; about independence of collecting, describing, and analyzing data from interpretation and theory; and about progress.

Until Kuhn’s “new philosophy of science”—or “history and philosophy of science”—the most influential responses to these problems were those

of logical positivist scientists and philosophers. While these scholars disagreed on many points, in general, the aims of what became known as the “received” or “standard view” were to analyze scientific concepts, relationships between evidence and theory, and scientific explanation on the basis of specialized language and logic. Emphasis fell on dividing scientific knowledge from other types of knowledge; fact from values; observation from theory; and contexts of discovery from theory falsification or confirmation (Salmon 1992). One of the most famous and controversial methods put forward is that called the “hypothetico-deductive” method, which centres on distinguishing between formulating a hypothesis, deducing a prediction that is amenable to observation, and performing an observation to see whether it confirms or falsifies the hypothesis.

For Kuhn, there were direct connections between obstacles the “standard” view posed for understanding revolutionary science change; and for creating a satisfactory philosophy of contemporary science. The history of science was, in Kuhn’s terms, an anomaly for the “received” philosophy of science. Kuhn clearly agreed with logical positivists and logical empiricists on key problems with traditional positivism and empiricism; and appreciated the extent to which the former scholars’ priorities grew out of convictions they developed under life-threatening conditions in Nazi-occupied Europe. However, Kuhn was concerned about the “standard” view’s a-historical (synchronic) picture of science. Its preoccupation with logic eclipsed dynamic diachronic relations between the contents and cultural contexts of science. With Kuhn, emphasis falls upon philosophical implications: the “standard” view was not able to account for revolutionary changes in the past and in the contemporary world. With Kuhn, changes in science that go against the grain of hitherto predominant paradigms for epistemology (methodology) and ontology (theory) call for “revolutionary” change in our understanding of knowledge, in general. Kuhn stressed that “scientific revolutions” are intrinsically historical, and that the historical contingency of science is a strength, not (as so often presupposed) an impediment.

Kuhn’s “scientific revolutions,” “paradigm,” “normal science,” and “incommensurable world views” all evidence these orientations. For Kuhn,

innumerable revolutions had occurred, especially in the formation of disciplinary specializations as paradigms. Scientific revolutions are not things that happened only in the distant past—they are happening today, with implications for change in our understanding of knowledge and the world we live in. From one day to the next, we may be responding to a “different world.” While the notion of a “paradigm” has many connotations, two figure especially centrally in the distinction Kuhn drew between the plurality of “scientific revolutions” and the “structure of scientific revolutions.” On the one hand, the concept refers to the “form of life” of a community. A research paradigm is what a scientific community shares—educational backgrounds, values, skills, and understandings of expertise and professionalism. On the other hand, the concept refers to exemplary models and normative criteria as resources that guide problem solving in “normal science.” For Kuhn, when a “paradigm” becomes seen as unable to solve decisive “puzzles,” it becomes an “anomaly.” Under “revolutionary” circumstance, the puzzles at issue become the foci of work on a new paradigm, and the old and the new paradigms concern “incommensurable worlds.”

Kuhn continued to work on diversity among disciplinary histories; and on what might be meant by “incommensurate worlds.” He stressed the importance of specialization to the sustainability of a new paradigm. In turn, specialization raises questions about diversity among the ways new specializations interpret a new paradigm. Kuhn focused particular attention on “incommensurate worlds” in *The Road Since Structure* (Kuhn, Conant, and Haugeland 2000): for instance, what is meant by the Copernican statement that “planets travel around the sun” cannot be expressed in the terms in which the Ptolemaic statement “planets travel around the earth.” This contrast compares with the ideas of a “gestalt” shift and “seeing aspects anew” of Ernst Gombrich and Ludwig Wittgenstein.

*“Scientific revolutions” as a paradigm
for archaeology’s disciplinary
historiography*

For many working in archaeology during the 1970s through 1990s, it may have been difficult to

imagine an era when the field had not been experiencing “crises over representation” and deep and far-reaching “paradigm change.” At issue was not the idea that research had been previously static. Emphasis fell on rates of change; and on the implications of new scientific technologies for addressing questions that had formerly been seen as intrinsically irresolvable, or not asked. Many categories, chronologies, and theoretical models that were previously treated as being of self-evident utility became characterized as belonging to traditional “schools of thought,” and as “anomalies” in the light of new findings and orientations. It was a period when the history and philosophy of science became a key area of archaeological specialization; and archaeology became a key area of specialization in the history and philosophy of science. It was the period when processual and post-processual paradigms diverged. Lewis Binford grounded much of his “new archaeology” in logical positivism and logical empiricism. Colin Renfrew sought variously to integrate aspects of these paradigms with insights drawn from Kuhn and David Clarke. Clarke’s (1973) paper “Archaeology: The Loss of Innocence” marked a turning point in the history of processual and post-processual paradigms. For Clarke, the adoption of scientific instruments and laboratory procedures developed during the two World Wars, vastly expanding available archaeological information. New technologies—in particular carbon-14 dating—brought light to anomalies in hitherto normative paradigms. They caused a “loss of innocence” about the ways in which archaeological materials had been used to address questions about the past. Clarke and Renfrew focused particular attention on anomalies in traditional pictures of European prehistory. The new dates showed that numerous events that had been treated as contemporary were separated by many centuries. The issue was not just about having dates wrong. The many arrows that had been drawn across maps of European prehistory to portray theories about the spread of peoples, ideas, and inventions from the supposedly “more advanced” Near East and Aegean to central, western, and northern Europe turned into anomalies.

In these views, archaeology was experiencing what Kuhn called “revolutionary” science change. In Clarke—as in Kuhn—plurality of scientific revolutions shaped disciplinary histories.

Clarke (1973) may have envisaged what he saw as the three key “thresholds” in archaeology’s disciplinary history along these lines—those of “consciousness, self-consciousness and critical self-consciousness” about archaeology’s philosophy of science. With Clarke, there is no such thing as a methodology independent of theory. Perhaps with Clarke (as with Kuhn) new paradigm sustainability hinges upon fostering lines of specialization (e.g., pre-depositional and depositional theory, post-depositional and retrieval theory, analytic theory, and interpretive theory).

Rethinking the notion of a singular scientific revolution

Up to this point, we have not stressed that the notion or image of *the* (singular) Scientific Revolution has a much longer and more problematic history than “scientific revolutions.” It is no coincidence that the above-mentioned changes have occurred in tandem with increased awareness that the former is a highly problematic image, calling for serious cross-disciplinary critical examination. Throughout much of the nineteenth and twentieth centuries, that image figured paradoxically among both the most and the least historicized presuppositions shared across the most influentially opposed theoretical traditions in the humanities: the most historicized, because it was assumed to figure among the prime movers of modernity, and was used as models for interpreting the diversity of cultures (and even human origins); and the least historicized, relating to notions of dichotomized truth versus contingency, and assumptions that contexts were already self-evidently known. Issues raised by Kuhn threw sharp light on these anomalies. It is unlikely to be a coincidence that major changes in approaches to these issues have been accompanied by efforts to rethink the problematic role that the image of *a* (singular) Scientific Revolution has played: for instance, as a key motif in generalizations about the supposed unity and distinctiveness of so-called western culture; and as a presupposition at the heart of such dichotomies as those of objectivity versus subjectivity, nature versus culture, and art versus science.

Today, much change in what discussions of “scientific revolutions” (and of the history and philosophy of science, in general)

emphasize is informed by the light these efforts are throwing on new questions: To what extent do the above-noted dichotomies (as well as highly problematic generalizations about “incommensurability”) hinge upon problematic pictures of both science and the supposed “disenchantment” of art history? What have been the circumstances under which responses to “crises over representation” have given rise to notions that we are forced to choose between such vexed options as either a deterministic order and Archimedean picture of knowledge or absolute chaos and hyper-relativism? To what extent have these (and related vexed options) eclipsed alternative options, and what are their implications for appreciating the jointly epistemic and ethical significance of incommensurability and alterity?

Current approaches and future directions

Even our brief examination of three manifestations of change in perspectives on “scientific revolutions” points to the continuously widening variety of approaches, and implications for future work. For instance, since the 2000s, the concepts of a “palimpsest” and “hybrid” have become widely used as tools for research on issues that have been eclipsed by divisions between studies of how things are made (their materiality) and studies of what things mean. These notions have special advantages for fresh approaches to the role of “practices” (or “use” in the widest sense of the term) in the dynamics of the material and the meaningful, and to the question of what is meant by a “context.” They invite us to explore the roots of problematic generalizations about so-called other world views (or modes of thought); and to appreciate the epistemic and ethical significance of experiences of incommensurability or alterity. Current studies that are engaging with the dynamics of materiality and meaning differ along an extraordinary variety of lines (see, for instance, MATERIAL CULTURE). However, one feature they often share with one another—and with Kuhn et al. (2000) and Emmanuel Levinas

([1961] 1979)—is a remarkable shift away from Archimedean notions of evidence. Instead, they envisage recognizing alterity and incommensurability as the very evidence that makes our understandings and experiences of evidence possible.

Substances and Materials

ANDREW M. BAUER

Stanford University, USA

Philosophers have theorized *substances* in many different ways, the range of which holds conceptual and practical implications for archaeological study and historiography. In general philosophical terms, one can equate substance to the primary entities of an ontological paradigm; that is to say that substances encompass the foundational components or abstract elements of a metaphysical framework. Descartes (1997), for instance, is well known for foregrounding body–mind dualisms and distinguishing the material substance of the world from the mental substance of thought. Thus, substances need not be strictly *material*. The “substance” or essence of abstractions or spirits, for instance, might be considered immaterial. In the more specific sense of an ontological framework that places primacy on particular substances (e.g., “substance ontology”), they are considered the basic materials, building blocks, particulars, or atoms from which artifacts and the world are produced, and are often qualitatively differentiated as distinct types of things or stuff (Robinson 2014). The notion of substances as different types of materials or stuff is commonplace in archaeological science and practice; indeed, it has strong resonance with molecular chemistry and how many of us conceptualize the aggregation of different elements in comprising durable things.

Ontological frameworks that emphasize the primacy of different kinds of substances stress the *intrinsic* attributes, dispositions, or nature of something. These dispositions are generally considered to be stable and a priori or independent of relations with other entities. In the context of archaeological lithic analysis, for instance, one might think of obsidian as having the intrinsic attribute of conchoidal fracture—that is, the stone holds that fracturing property before it was

ever struck by some other hard object to produce a tool, waste flake, or scar. An ontological framework that gives primacy to substances with inherent and predictable properties has significant epistemological implications for archaeology. For instance, conceptualization of obsidian as a particular kind of material substance with stable fracturing properties allows archaeologists to apply practical and technical understandings of stone tool production derived from contemporary *experimental archaeology* to make inferences about how people fashioned the same material in the past or the chain of operations of tool production. Mechanical understandings of substances as holders of predictable behavioral properties also open space for specific conceptions of human agency in shaping the world, given the degree to which they can be worked, crafted, and arranged according to human intentions, plans, or desires. Yet ontological understandings of substances that privilege their inherent nature and stable attributes can also lead to ahistorical and presentist arguments about the past, such as the view that “precious metals” like gold and silver are essentially valuable, regardless of cultural and social context.

Substance ontologies are often contrasted with *relational ontologies*. Relational ontologies privilege interactions and make shared relations among metaphysical entities more foundational to the nature of being than essences or individualized particulars with inherent attributes. With respect to archaeology, it is important to note that relational ontologies would place fundamental emphasis on the situations and contexts in which things occur and articulate with others. For instance, one might think of a marble sculpture and an organic grain of rice as composed of different kinds of stuff—one that is inherently more enduring and stable that comprises the sculpture and another that is inherently impermanent and fragile that comprises the grain. Yet, in certain contexts—for example, where there are high amounts of acid rain and sulfur dioxide air pollution—marble quickly disintegrates, and in others—for example, waterlogged anaerobic

conditions—organic material may persist with minimal alteration for thousands of years. Their properties are contextually or relationally dependent, and thus one kind of material is not innately more durable than the other by virtue of its substance or essence. While philosophers inclined toward a substance ontology may argue that these properties are simply “secondary” to an underlying (unchanged) substance that, by its nature, affords such apparent transformations, relational ontologies stress the relationships themselves as fundamental: Shifting relationships change substances.

By calling attention to relationships, relational paradigms are amenable to process-based philosophies that foreground interactions and consider the nature of being as fundamentally dynamic. They are often evoked with the concept of an *assemblage* developed by philosopher Gilles Deleuze. Jane Bennett (2010), for instance, argues for the “vitality” of matter in considering material *actants*—a term borrowed from philosopher Bruno Latour to refer to entities that are sources of action and often *mediate* or “modify a state of affairs” (e.g., Latour 2005, 71)—as part of broader assemblages that dynamically give shape to the world and contribute to human social and political histories. Assemblages are temporary configurations of heterogeneous elements that, through their historical configurations, produce *emergent* outcomes—which is to say that their effects are not merely the sum of their parts, nor are they reducible to individualized properties. Bennett uses a blackout as an example, suggesting that an electrical blackout might productively be considered the outcome of the specific conjuncture of a multitude of energy consumers, material networks (e.g., electrical transmission wires, downed power lines), “reactive” power that is necessary to maintain transmission voltage (but that dissipates over long distances), and government regulations that do not incentivize energy providers to generate “reactive” power over “active” power. Here it is important to note that theories of causation and emergence might productively consider substances and relations in tandem.

The work of Bennett and others (e.g., Coole and Frost 2010) is representative of a suite of scholarship, often termed *new materialism*, that de-privileges humans in giving shape to

social history and artifacts. These frameworks have explicitly questioned the exceptionalism of human agency by positioning human actors within an assemblage, collective, web, or grid of other material things, substances, or forces that affect activities, social relationships, and historical outcomes. In this sense, renewed theorization of substances and materials as dynamic and active has called attention to the limits of human agency and how its theorization might be decoupled from longstanding links to individual, rational actors. Moreover, much of this scholarship stresses that things are not fully reducible to the meanings that people associate with them, and that the active qualities of materials need not conform to human will or intentions. These emphases are compatible with other anthropological and archaeological approaches that have stressed the embeddedness of humans and their environments, such as those deriving from phenomenology. The anthropologist Tim Ingold (2000, 77), for instance, has argued against the notion that humans simply impose mental templates or designs onto materials in craft production; instead, he suggested that the fashioning of artifacts should be considered a process of “growth,” similar to how raising crops or animals involves interactions among a multitude of materials and organisms (rainfall, pests, etc.) that practically constrain, condition, and shape material outcomes. Artifacts “emerge—like the forms of living beings—within the relational contexts of the mutual involvement of people and their environments” (Ingold 2000, 88). Such concerns explicitly call attention to how the dynamics of substances are important to the crafting of material worlds and historical processes, opening up a range of possibilities for the archaeological sciences to contribute to broader conversations in the humanities and social sciences.

Archaeology, of course, has a long history of considering the role of environmental materials and relationships in shaping human history. For instance, the “economic approach” advocated by Grahame Clark (1953) in the mid-twentieth century emphasized the environmental constraints and possibilities related to human subsistence choices, suggesting that cultural development increasingly expanded the possibilities for economic activities while simultaneously calling attention to feedbacks between these activities

and physical ecological limits on production. Moreover, the New Archaeology that developed throughout the 1960s and 1970s borrowed heavily from ecological paradigms of anthropology (e.g., cultural ecology) and often considered the distribution of subsistence resources (e.g., water and game) as giving shape to cultural land-use and social organization. In these frameworks, the dynamics of the environment, such as climate change, were frequently linked to cultural change as resources shifted and people were forced to adapt. Renewed emphasis on the dynamics of substances, or more precisely *relational substances*, have reinserted the importance of material dynamics into the mechanisms of historical change—although often at different scales and with more contextual nuance and complex determinative logics than earlier approaches.

Paradigms that consider substances to be “vital” (*sensu* of Bennett 2010) have called attention to how the “actions” of materials frequently provoke or require subsequent human actions. For example, Ian Hodder (2012) has cogently argued that once humans begin to depend on specific materials as resources—such as clay for constructing walls—they become trapped, or “entangled,” in relationships of dependencies in which the properties and behavioral interactions of substances condition human activities. As construction materials weather and erode, they force humans to maintain them and create relationships of “care, regulation, and discipline” (Hodder 2012, 78). In that sense, it has been argued that the interactions of materials have a form of “primary agency” in shaping human social history.

Theorizations of historical processes that stress the significant role of substances in engendering certain social activities open up important space for the archaeological sciences to contribute to “new materialist” historiographies. Many analytical techniques of archaeological science document the past actions of materials—that is, how they physically behaved in specific contexts. For example, by examining soil and sediment structure, texture, and composition, geoarchaeologists can document the alteration or stability of land surfaces, the relative energy involved in water and wind transport and deposition, and the movement of mineral matter from source to

destination. Similarly, soil micromorphological analyses document a range of soil features and formation processes that further underscore the transmutation of materials in archaeological contexts, documenting the weathering of minerals and the formation of others, the shrinking and swelling of clay, and the translocation of materials in soil profiles. Such observations effectively detail the dynamics of soil as an outcome of interactions among heterogeneous constituents and provide important links between recording the properties of materials and the social history of landscape production.

Placing emphasis on the “actions” of relational materials and the cultural contexts in which things are differentially valued might open fertile ground for new emphases in archaeological historiographies that rely heavily on archaeological material sciences. Borrowing the term from geomorphological studies, Bauer and Kosiba (2016) refer to a process of “entrainment,” whereby materials that are “caught up” in the flow of human activities have the potential to affect politics and social change. In the context of the South Indian Iron Age (1200–300 BCE), for instance, they argue that the cultural value placed on herd animals heightened the social and political consequences of soil erosion, which shifted the distribution of herding resources and contributed to the emergence of social inequalities during the second and first millennium BCE. The current interest in relational ontologies and process-oriented philosophies toward materials might productively call attention to what things physically do in specific contexts, as well as how their social and political effects are also context dependent, conditioned by historical values and differentiated perceptions and understandings of environmental phenomena among humans. Such frameworks open opportunities for explicitly considering the historical process as neither exclusively culturally nor environmentally determined.

Symmetrical Archaeology

CHRISTOPHER WITMORE

Texas Tech University, USA

Throughout the history of our discipline, qualifying adjectives have been added to archaeology in order to distinguish a particular approach or doctrine and its adherents from what was framed, whether critically or rhetorically, as the “normative mode” of practice, of interpretation and formulating questions. Symmetrical archaeology did not set out on this familiar path. It began as a modest proposal to remember those increasingly neglected nonhumans relegated to the wings as props for humans-among-themselves, what archaeological practitioners viewed as the privileged protagonists in the “social” spectacles that comprised past worlds (Olsen 2003). Symmetrical archaeology eschews that critical gesture of dialectical one-upmanship that would relegate other practices, concepts or questions to the realm of the outmoded (González-Ruibal 2007) and avoids that disciplinary amnesia associated with such a paradigmatic image of progress. Rather than exaggerating differences with other subdisciplines, symmetrical archaeology excavates to what is common for archaeologists everywhere—things. Thus it is not a unified theoretical platform. It can best be characterized as a series of propositions for approaching ceramic-laden fields, ruined Byzantine structures, or buried middens, and generating more faithful, more inclusive accounts where things, what has become of pasts, are recognized as mediators rather than mere intermediaries; where pasts are not separated off from any present by ruptures or revolutions (something reinforced by an image of a linear, successive, and externalized time), but linger amidst perishing, gather amidst dispersion, and endure amidst transformation within a dynamic ecology of coextensive actual entities in the present. Whether practitioners choose to see symmetrical archaeology as eschewing that oversimplification of diverse entities into two purified

domains or as an altogether different metaphysical commitment, it is worth repeating that the adjectival label was always recognized as provisional (Witmore 2007, 547; Olsen 2012, 223).

Symmetrical archaeology derives its adjective from the principle of symmetry. If we are to avoid a double standard where the scientific practices behind the Clovis-first hypothesis (a now disavowed consensus, which held the prehistoric Clovis culture to represent the first peoples in the Americas) are treated a priori with utmost certainty, while indigenous methods for detecting a deeper ancestral presence in North America are regarded with absolute incredulity, then truth and falsity, fact and belief, successes and failures, the new and the outmoded have to be explained in the same terms. Whereas the first principle of symmetry remained asymmetrical by seeking explanation in the realm of society, a more generalized principle of symmetry boldly trudged across the great divide to include what had been purified as “nature” and left to the natural sciences (see Latour 1993, 91–6). Symmetry serves to remind practitioners not to decide in advance what role various entities play in a given situation by imposing arbitrary hierarchies of value or preformed dogmas concerning the nature of the real. Reservations about the term “symmetry” have been voiced repeatedly, and misunderstandings abound (see Olsen and Witmore 2015). It is not that everything goes, but what is relevant in a given situation cannot be sorted out without substantial labor. Symmetry is best conceived as an agnostic disposition, a guideline, a principle, or even an attitude (Shanks 2007); it is not an ontological maxim that undergirds all being. Symmetry does not imply that all entities exist equally—asymmetries are legion—rather it suggests that all entities be equally granted dignity as things.

Initial forays into symmetrical archaeology regarded things, “those enormously varied physical entities, ... [as] beings in the world alongside other beings such as humans, plants, and animals” (Olsen 2012, 212). Positive emphasis was placed on “thing” in its etymological sense of

DOI: 10.1002/9781119188230.saseas0563

“gathering.” Even the smallest of the individual limestone blocks within the polygonal walls of the Argive Aspis is a co-realization of limestone form in relation to other forms, the purpose that is the pride-infused wall, and skilled stonemasons with hammers and chisels. Relations, moreover, between stonemasons and polygonal walls are no more and no less important than the relations between individual blocks, foundations and tree roots, or pride-infused enclosures and the Argive polis. If any of these beings makes a difference in a given situation, then it is “actant,” and an actant is no more and no less important than other actants at the start of an analysis. While this analytical leveling opened the door for understanding the diverse mediating roles of nonhumans, it left it ajar for others to reassert orderings of the world on the basis of pre-ordained taxonomic divisions, whether as humans and the rest or vital and inert entities, even though symmetrical archaeology patently rejects such radical separations. It is also the case that an emphasis on relations and agencies is asymmetrical so long as it misses other properties of things—not only those aspects that surface *for us* or *for others*, but also what is intrinsic to things, the *in itself* (Olsen 2010).

Symmetrical archaeology radically reconfigures the definition of things, not as objective matter against subjective qualities, not as the relational opposed to nonrelational, not as the nonhuman counterpoised to the human—things have no opposites—but rather as autonomous entities or units that cannot be broken down into their components or reduced to their effects (Olsen and Witmore 2015, 191; Witmore 2014, 4). Neither materials nor ideas nor abstractions are to be relegated to the sidelines, for this would directly violate the principle of symmetry. Former gateways and streets are no more and no less things than the goddess Demeter or the psycho-political wellbeing of a Hellenistic polis. While one thing is not derivative of another, this does not imply that all things exist equally. Polygonal walls and limestone exist differently from erstwhile stonemasons or microorganisms precipitating on the seafloor 100 million years ago.

Symmetrical archaeology does not provide a ready-made theory to apply across diverse situations. Things resist our attempts to grapple with them, to articulate them, or to explain any

of them in terms of something else. Thus, it stands in defense of the otherness and integrity of things against approaches that subject them to sameness, where, for example, an overemphasis on the construction of authority makes Chaco Canyon sound like Chavin-de-Huancabamba. This commitment is also related to an ethical issue of care and devotion to things for what they are in their own being. Symmetrical archaeology, therefore, aims to flush out idiosyncrasies by articulating the positive differences between the legion things present at these sites, which may lead to richer and more compelling narratives (Olsen 2012, 213; Olsen et al. 2012, 13–14).

Symmetrical archaeology asserts that archaeology studies a bewildering variety of things in the present rather than the human past through its material remains. It is a “fallacy of expression,” for any symmetrical approach, to situate the agency of Roman soldiers a priori behind what lies before archaeologists in an open field. Neither the past nor the material past is the starting point for archaeology; rather, the erstwhile angle is part of the solution. While this is partially related to a classic issue of assumed versus justified identifications of archaeological things, things do not gain their reality from elsewhere—succinctly, what has become of a Roman fort is involved in the realization of its past in the present. Symmetrical archaeology does not turn its back on humans or the past; rather it submits that the full price for any account of what was, tentative and risky as it is, must be paid. If abandoned surfaces cannot be reduced to an erstwhile equestrian barrack, animal enclosure, or ruin, then painstaking work must be done to explain one in terms of the other. In order to connect a portion of polygonal walling to the psycho-political wellbeing of a Hellenistic polis, significant labor must be invested and this work is always open to reassessment.

Narratives concerning the past, and even the material past itself, are what archaeology achieves. The question of how to proceed belongs to a wider field of possibilities, to the creative adventure that is archaeology. Because relevant questions surface in the course of our practices, our achievements should not be severed from the labor that led to them. Indeed, archaeologists do not stand apart from the world that they seek to better understand. Many early examples

of symmetrical archaeology were concerned with a problem-oriented set of emphases that included a focus on mediating roles of things within a localized process of doing archaeology. Symmetrical archaeology recognizes how every achievement is realized within a very specific ecology of practices, comprising institutions, instruments, affiliates, knowledge design, and the like, and some studies have gone to great lengths to demonstrate how the past is co-created with legion entities. Because the world cannot be reduced to a scheme where humans maintain a 50% share in reality, archaeological theories, stories and ideas comprise but a portion of archaeological labor and achievement. Succinctly, what things are willing to share regarding their erstwhile existence is best understood as a species of memory (Olsen 2012). Memory is an involuntary aspect or quality of things and is related to their own capacity for manifesting their pastness to us. Therefore pasts belong as much to middens or abandoned turf enclosures in a camp as to those PoWs or guards that archaeologists may seek to better understand.

Symmetrical archaeology is an inheritor of that longstanding archaeological aspiration to dig to what is fundamental as our objects of study, but not at the expense of sorting out what is real and what is not in advance. It aspires not so much to greater certainty as to making positive gains amidst every present uncertainty. Its stories are diverse, from gatherings of different times in the fabric of Greek city-states, Ethiopian landscapes of abandonment to material memories present in a PoW camp in Finnmark, Norway. Ultimately, symmetrical archaeology strives for an archaeology that is not subsumed to history, but is equal in scope and thus stands as both its complement and alternative.

Time and Temporality

SEREN GRIFFITHS

University of Central Lancashire, UK

Archaeology can be defined by its emphasis on the time depth of its study, the importance of the passage of time, and material culture. To this we might add an interest in a multiplicity of narratives—in terms of both narratives that make space for multiple interpretations of material culture and narratives produced from things that tell stories of people that might not be accessible from more conventional histories. Time provides one means along which archaeologists can arrange and structure their narratives. The details of different time measurement systems will not be explored here, but the implications of applying these schemes will. Different methods for the documentation of the passage of time have often marked important developments in the discipline, in terms of our understanding of the natures of things and of writing about change and the causal mechanisms we employ. These developments have sometimes been allied to other areas of research: for example, the importance of Charles Lyell's work on stratigraphy and geological principles in the nineteenth century.

Archaeologists look for patterns in the distribution of material culture over space and time. These patterns are indicative of previous peoples' choices and behaviors, and preservation and excavation bias. Because all material culture exists and is studied in the contemporary world, archaeologists sometimes perceive that the spatial distribution of things is relatively simple to document. Reconstructing how things have existed over time outside our present experiences of them has presented more difficulties for archaeologists. How to represent and order the time dimension of archaeological study has therefore been one of the key themes of the discipline. This goes beyond the quest for the "first example" of this thing, or the "oldest known case" of that thing, though often it is "the firsts" and "the oldests" that

make headlines. The schemes that archaeologists use to order things along the time dimension of their study in part reflect our contemporary understanding of the natures of things. When we produce order through our classificatory schemes we reproduce or reflect our fundamental understandings of the structure of knowledge. Temporal ordering schemes can therefore allow archaeologists to suggest new patterns and potential causal relationships, but they also structure how we think about past societies and how we can talk about or describe past societies.

One of the most fundamental developments in archaeological thinking was the formalization of the Three Age System. This is an Old World scheme for organizing taxonomically artifacts by their material properties, and using this order as a proxy for the passage of time. Such schemes have old antecedents: for example, in the ideas of Lucretius about the development of human societies over time. The Three Age System represented an important development in nineteenth-century thinking and organization of archaeological material into Stone, Bronze, and Iron Ages (Gräslund 1987). Formalized by C. J. Thomsen in his role at the Museum of National Antiquities, Copenhagen, the scheme quickly led to the development of chronologically defined subdivisions by scholars such as J. J. A. Worsaae in Denmark and John Lubbock in Britain. With the development of these schemes came the bones for all subsequent archaeological studies, which have latent at their hearts themes of linear, directional, or teleological sequences or development over time. These approaches also saw the beginnings of a continuing concern among archaeologists to deriving increasingly well-ordered and precise chronologies.

If the formalization of the Three Age System in the nineteenth century provided the background for archaeological thought, it was a pioneer of early-twentieth-century archaeological thought who took these schemes to their most developed fruition. V. G. Childe's work organizing the culture historic model of European prehistory provided the intellectual framework for modern archaeological approaches. Culture history

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

DOI: 10.1002/9781119188230.saseas0581

schemes approach assemblages of material as indicative of the presence of groups of people defined as archaeological cultures. Variation within these groups is glossed over within cultural “blocks” which are delineated in space *and* time. Childe’s strengths lay in his ability to synthesize and organize large volumes of evidence from wide areas of Europe. His culture history tables provided essential clarity and order in studies of prehistories where, prior to the advent of scientific dating, typologies (associated with other contextual information) were the only ways of providing a narrative structure.

As a means of domesticating and organizing the past, these approaches are invaluable, but they are also limiting. The time dimension in these approaches takes on a series of very specific qualities. First, as identified as monolithic units, the potential for change in archaeological cultures seems difficult, and archaeological cultures become seen as static. Second, the ordering—the sequence of things in the time dimension—predetermines how things happened in “the past.” Third, because these schemes are defined by our contemporary understanding of the nature of things, they say much more about contemporary knowledge systems than necessarily changes in material culture over time, or previous knowledge systems. Culture history approaches emphasized critical differences between assemblages, and this left it open to bias and subjectivity in the treatment of the schemes. This was not simply in terms of which traits in cultures were the most important to record, but also they structured the fundamental organization of these schemes. An example will demonstrate how situated these systems are. When Childe was developing his culture history schemes of northern Europe, it was received truth that European cultures always developed out of “Near-Eastern” ones. In part this approach derived from the model of change employed in culture history narratives; typology determined that traits or types of materials developed one from the other. Traits could therefore be tracked as they diffused from the point of origin outwards. Childe at one point developed two schemes for European prehistory, but adopted one which positioned the European Neolithic megaliths after the Near-Eastern one *because* of this universal relative truth. It was not until the development of radiocarbon dating that

a model of diffusion *ex oriente* was demonstrated to be incorrect. With synthesis and organization came the tendency to draw lines through the aspects of the culture history schemes with most ambiguity. A corollary of this is that the differentiation between abstract taxonomic “blocks” of culture has quite a specific set of implications for temporal change in narrative structures (see below).

Developments in excavation approaches often occurred in the form of more sophisticated ways of documenting physical proxies, which on archaeological sites stand in lieu of the passage of time. Thus, Mortimer Wheeler’s grid system provided spatial control in plan, and multiple samples of the vertical nature of deposits which stand for change over time. The Harris Matrix approach to recording was developed to schematically represent archaeologically observed relationships among the different deposits, negative features, and structures which provide spatially defined analogs for the passage of time. Single-context recording systems employed in British archaeology seek increasingly accurate and sophisticated representations of observed physical phenomena on the ground as a means to document things that stand for the passage of time.

While all these approaches attempt to document more accurately observed phenomena, all are highly speculative and situated, as Ian Hodder’s famously observed interpretation begins, at the trowel edge. All of these approaches attempt to document in the production of the written, drawn and photographed archaeological record evidence which we can equate to processes that occur over the passage of time (Patrik 1985). As such, space on site becomes the means of documenting evidence for the passage of time; as with the physical properties in artifactual culture history typologies, space now becomes analogous for time then. Attempting to understand the problematic timescale returns in many cases to models that use spatial characteristics to distribute order, and this process is problematic. While doing so, spatial models often abstract representations of time, so that site phase plans reduce activity (the “Iron Age”) to a two-dimensional, spatially defined model. The use of such visual iconic analogs—as David Clarke termed them in his 1973 book *Models in Archaeology*—does much to flatten the interpretation of activity that might have

occurred over various different durations, with obvious implications for our narrative structures.

A tendency to flatten and abstract time on individual sites is arguably compounded by a continued reliance on period-defined, sequential, culture historic models. Culture history models maintain an importance in archaeological narratives to varying degrees in different parts of the world, but they are also the latent narrative structure in any archaeological discussion that employs these terms as proper nouns; if you excavate on a site and you are looking for the “Bronze Age,” you are excavating within a culture historic scheme, with all the potential for contemporary narrative bias as Childe’s model of north European megaliths post-dating those in the eastern Mediterranean. These culture historic approaches are incredibly pervasive, despite the clear problems with the normative idea that groups of material culture can be equated with specific groups of people, and the problems of envisaging culture defined spatially with an absence of change, diversity, and variability. They remain the basis for archaeological temporal thought decades after the realization that these models were problematic (Thomas 1996, 97), even in areas where archaeological theory has called for more sophisticated approaches as part of a material-turn in intellectual thought.

A further issue can exist in terms of attempting to identify patterns in material culture over space and time that are indicative of previous peoples’ choices and behaviors. In many regions, a tendency for a culture historic approach to material culture (identifying things as indicative of a set of behaviors associated with a group of people) is compounded by a chronological definition for the lifeways under discussion. In Britain, for example, “the Neolithic” (defined as a suite of material culture and practices) is often defined as beginning at a calendar point in time. Here we see a conflation of what archaeologists should be investigating (patterns in material culture over space and time) with the scales along which we organize our evidence (specific points in time; the spatial unit of analysis). The archaeological concept of the culture has here become a thing itself, and the evidence for the systems that we should be using to organize it mean that archaeologists very obviously risk structuring their causal

narratives with their contemporary epistemologies. This is a logical fallacy; defining culture by a time unit and/or an archaeological concept will predetermine our narratives (Griffiths 2017).

This tension between the subject of archaeological enquiry (different distributions of material culture defined in space and by proxies for time) and the normative culture historic categories we employ is a conceptual tension, not a clash of chronological systems (Lucas 2005, 9; cf. Griffiths 2017). Among many contemporary archaeologists there is an assumption that periodization more or less remains empty of its original narrative content and is largely a relative chronology devoid of specific meaning (Lucas 2005, 50). For a discipline that has strong emphasis on ways of observing the passage of time, our lack of attention to the structuring role of chronology in our narratives is perhaps surprising. One of the few archaeologists to recognize the inherent issues with these temporal tensions is Ann Ramenofsky (1998).

Ramenofsky (1998) emphasized the importance of differentiating time, the units of measurement of time, and the structuring model organizing these units; it is always essential to regard chronology as a conceptual, imposed model of evidence for the passage of time. Many of the underlying causal narratives that are invoked in archaeology could derive from inaccuracy in the orderings of chronologies, or in terms of chronological imprecision being mistaken for correlation. Ramenofsky differentiates between ordinal (e.g., culture history-inspired periodizations) and interval (e.g., radiocarbon years) temporal data. The tensions between narratives that are played out using these different schemes but where archaeologists have not understood that they are employing distinct datasets brings to mind Stuart Piggott’s famous appraisal of the then-new radiocarbon measurements from Durrington Walls, which he deemed archaeologically unacceptable. In short, like Childe’s view of the Near-East pre-dating northern European megaliths, or Piggott’s view of the Durrington Walls radiocarbon measurements, ordinal chronological data can be significantly at odds with interval chronological data. Because the mistakes that Childe and Piggott made now look so obvious, and many contemporary archaeologists have access to more interval (radiocarbon

or other scientific) measurements, it would be arrogant in the extreme to believe that we as contemporary archaeologists are inured to such oversights, when many contemporary archaeologists employ as their basic ordering systems culture history-derived ordinal schemes.

A different discussion of the influence of temporal resolution has been espoused by Geoff Bailey with his “time perspectivist” approach. A central theme of this approach has been the importance of the palimpsest, and attempts to unpick the time-depths of different anthropogenic and sedimentological elements that comprise an archaeological site. This approach would argue that the structural temporal properties of the materials that comprise archaeological sites fundamentally limit the kinds of questions that archaeologists should attempt to explore; that the time scale—the perspective—will change the causal mechanisms employed, with some processes only visible on longer and coarser timescales. An additional theme that overlaps with other archaeological approaches to time is that the subjective conception of time is culturally specific (see below).

In contrast to schemes that order and organize the division of time, significant emphasis has been brought to bear by archaeologists on the more experiential properties of time. These have included approaches to portable material culture, sites, or landscapes (for example by Christopher Tilley), including an emphasis on the importance of the past in the past (for example by Richard Bradley) and the importance of perceptions of time in other cultures (e.g., Gell 1992). Much of the archaeological concern with temporality can be traced to the use of the term in the paper published in 1993 by anthropologist Tim Ingold entitled *The Temporality of the Landscape*. The impact of this paper on archaeological writing can be identified by the frequency with which it is cited.

Ingold’s paper takes as his point of departure the discussion of a landscape painting by Pieter Brueghel the Elder, *The Harvesters*. Describing the processes on-going in the image, Ingold attributes temporality to various aspects of the landscape and coins the term *taskscape* to describe his approach. This concept has been highly influential. However, the approach brings us back to the importance of narrative in temporal approaches; arguably, the subjects of the image—continuously

suspended in their existence forever—do not quite successfully achieve a temporality without Ingold as negotiator.

The use of the archaeologist as the narrator or magus to animate the past has produced some evocative archaeologically thick descriptions, especially of landscapes. Temporality is often written of in terms of the experiential quality of material culture, or the enduring or durational qualities of aspects of the archaeological record. Laurent Olivier’s (e.g., 2001) work on this theme emphasizes such things as multitemporality and enduring things, and a continuity with pasts that do not exist, in opposition to “the present,” which Christopher Witmore has described as percolating.

Approaches emphasizing the past in the past have extended to sites, landscapes, and objects—for example, a Neolithic axe in a medieval house floor—and have provided rich themes for archaeological writing. Emphases on the importance of the perception of the passage of time and the importance of different magnitudes of temporality have often been used as ways of *explaining* or adding causal rationale to practices in the past (often with the idea that value is attached to the already old as powerful, magical, or potential with associations with the ancestors, authenticity, and so). These approaches marry into ways of writing about material culture that take an object biographic approach. At the center of these approaches is the idea that things’ natures can accrue and be transformed over their life cycles. Biographies of things include their creation and “life” courses, as well as identities derived from the network of relationships with people and other agents. The temporalities of things are therefore not simply defined in a time-linear manner, but might be understood as the temporal qualities in terms of the worldliness of things.

The realization that temporality has significance leads us to the obvious corollary that temporality will have different significance, symbolism, and symbolic value in different social systems. More anthropologically informed approaches to the temporality of landscape and things have led to considerable interest in the range of ethnographic examples of how time, chronology, and temporal change are marked, represented, and understood (e.g., Gell 1992).

There have been numerous classic anthropological examples that detail these examples, though there is a common stress on the perceived directionality of the passage of time and usually its linear (though frequently the cyclical) career. These studies have stressed that in human terms the experience of time—and especially of time associated with valued or charged social contexts, such as with rites of passage or ceremonies—can have different or special qualities.

Related to the anthropologically informed emphasis on the specificity of time schemes have been archaeological approaches to the political dimensions of time. Perhaps the most optimistic and subtle version of this was work in the 1970s by Mark Leone, which explicitly drew attention to the ways in which contemporary archaeological practice was structured by our temporal understandings, and how other societies might equally be enmeshed in their temporal rationale.

Archaeology as a subject that looks for patterns in the distribution of material culture over space and time, and attempts to analyze these as indicative of previous peoples' choices and behaviors, is wedded to the importance of time as an axis of analysis, and temporality as a means to approach other peoples' worlds.

Airborne Laser Scanning and Lidar

NICK HANNON

Canterbury Christ Church University, UK

Lidar has become a standard tool of the landscape archaeologist, its name being a portmanteau of **light detection and ranging**. In archaeological publications, lidar is commonly used to describe airborne laser scanning (ALS), with terrestrial laser scanning (TLS) normally being referred to as three-dimensional (3D) laser scanning, although both ALS and TLS use similar lidar technologies. For the purposes of this entry, lidar refers to ALS. Lidar was first developed in the 1960s, although simpler devices with similar principles were in use before this date; but it was the 1990s before lidar was first applied to archaeology. The principle of lidar is relatively simple; a pulse of infrared or near-infrared light is fired at the ground from an aircraft. Fixed wing airplanes, helicopters and unmanned aerial vehicles (UAVs) can all be used to carry the lidar sensor. The length of time the pulse takes to reach an object and be reflected back to the sensor is then recorded. Using the speed of light, the distance the pulse has traveled can be calculated. Converting this basic principle into a technique that can be used to provide highly accurate 3D measurements is a little more complicated.

Lidar sensors generate between 20,000 and 100,000 pulses of light each second. These pulses are emitted in a side-to-side sweeping scan as the aircraft travels forward, creating a wedge shaped scanning area beneath the aircraft. This produces a measurement density of between 1 and 20 points per square meter, although the altitude of the aircraft will affect this density. Establishing the position of the aircraft is essential, as the sensor needs to know exactly where it is measuring from, therefore a global navigation satellite system (GNSS) is used to record the position of the sensor multiple times each second. The GNSS

receiver is in constant contact with a number of known points on the ground known as ground stations. To maintain a high level of accuracy, the aircraft needs to remain within 30 km of one or more of these ground stations. A further consideration is the small variations in altitude, pitch and yaw of the aircraft encountered during flight. To correct for these movements the aircraft carries an inertial navigation system (INS), which records these variations. So by combining the speed of light calculation to obtain a distance, the angle the pulse is emitted and the exact position of the aircraft, to establish position, a point cloud is created. This point cloud contains a number of 3D points representing the surface beneath the aircraft.

Complementing the spatial measurements, the sensor can also record additional data including the intensity measurement; this is quite simply the percentage of light that the target surface reflects back to the sensor. Intensity measurements can help to differentiate between different objects being sensed due to their variable reflective properties; this can assist with point classification. It has been demonstrated that subsurface archaeological remains can affect the reflective properties of the overlying vegetation in a way comparable to the formation of crop marks (Dèveux et al. 2005); thus the intensity measurement can be utilized to detect subsurface archaeology. Some sensors are also capable of recording the color of target objects as red, green, blue (RGB) values, so seven measurements can be associated with each point in the cloud:

- x coordinate
- y coordinate
- z coordinate
- intensity
- red
- green
- blue.

A well-acclaimed capability of lidar is its apparent ability to “see through trees”: a facility lacking in comparable techniques like aerial photography or satellite remote sensing (Challis

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

DOI: 10.1002/9781119188230.saseas0011

et al. 2011). This is achieved by utilizing the fact that when each pulse of light is emitted by the sensor, instead of persisting as a single point of light, it gradually spreads out, similar to the beam of a torch. When the beam reaches the surface it will have a diameter of around 0.1 m if emitted from around 1,000 m. As the light approaches a wooded area, some is reflected by the crown of the canopy and returned to the sensor; this is the first return. Further portions of the light are reflected at various levels within the canopy; these are intermediate returns. A small portion of the light may reach the ground before being reflected; this is the last return (although the ground is not reached in all cases and the last return may occur within the canopy). The phenomenon of multiple returns is what enables lidar to model both the woodland canopy and the ground surface beneath. A surface generated from first returns is a digital surface model (DSM), and one generated from only last returns that have reached the ground is a digital terrain model (DTM).

Unprocessed lidar data are normally available in the industry standard .las or .laz format; this contains a 3D position along with intensity and RGB data for each point. This format contains the first and last returns along with a number of intermediate returns, as determined by the capability of the chosen sensor. In a limited number of cases the entire return profile is recorded: this is called full-waveform lidar. Full-waveform data has the advantage of allowing more control when attempting to separate tree cover from the ground surface, potentially producing better results. Complementing the unprocessed lidar data, pre-processed products are available: these are delivered as raster data in .tiff and .asc formats, in vector format as a .xyz file, or pre-hillshaded images in .jpeg format. They are supplied in both DTM and DSM versions generally as 1 km² or 0.5 km² tiles. The use of pre-processed data allows researchers to bypass the data-processing steps, as it is delivered pre-filtered and pre-rasterized. This allows the project to immediately proceed to the visualization and interrogation of the data, but removes any control over how the data are filtered and converted into a raster.

If unprocessed data are used, it needs converting into an archaeologically useful form. To achieve this, numerous steps need considering,

the specifics of which vary depending on the software package used; therefore the following is a general outline of the process. The initial step is point classification; this is a process by which the multiple returns from each pulse are grouped in a meaningful manner. For archaeological purposes the important group is the “ground” classification. Classification involves the use of algorithms to differentiate ground points from final returns occurring higher in the canopy. Numerous algorithms are available that generally look at a radius of points around the one being analyzed, establishing how they relate. If the point would cause a sharp unnatural change in topography it will be considered a mid-canopy reflection, whereas one at a similar elevation is considered a ground return. Numerous passes are made with these algorithms until a relatively smooth ground surface is achieved. These algorithms have user-definable values so the search radii and the angle considered shape are tailored to suit the wooded area’s terrain; however, over-processing can have the effect of hiding archaeological features.

Once the ground points are identified the processor will have to decide either to retain the data as a vector, or to convert into a raster format; this depends on the end product required from the lidar. If this product involves the presentation of a 3D surface in a virtual environment, then retaining the data in a vector format may be preferable. To achieve this, the ground points need converting into a triangular irregular network (TIN); this process involves joining the points with straight lines, creating a series of triangles. These triangles will be larger in areas with low point density and smaller in high-density areas. The TIN’s advantage is that the file size generated is relatively small compared with that of a comparable raster, and as none of the points are moved, a TIN retains high spatial accuracy. The disadvantage of this method is that the spatial analysis and visualization options are more limited than are available for rasters.

The alternative to the TIN is to convert the point data into raster format, which involves fitting the data into a regular grid; again this involves making a number of decisions that may affect data quality. The resolution of lidar data is normally quoted as points per square meter, but when viewed from above the data

are not evenly distributed. This unevenness is partly caused by the undulations of the Earth's surface, partly by the movement of the aircraft and partly by the number of points filtered out during the classification process. The next stage of the process is to decide what size each cell in the grid should be. The smaller the cell size, the higher the resolution, but this will result in a larger file size. A cell size is normally chosen which is similar to the average spacing of the points, although a larger cell may be chosen if there is a large standard deviation in the point spacing or to reduce file size.

When a grid is imposed on unevenly distributed points it will result in some cells containing multiple points, some containing only one, and others containing none. The next stage in the process is to allocate a numeric value to each cell. To generate a DTM the point's z-value is used; alternatively, for an intensity visualization it will be the i-value. For cells only containing a single point, this process is relatively simple—the value of the point is transferred to the associated cell. However, for cells containing multiple points it is more complicated. For archaeological purposes an averaging approach is generally preferred. This generates a mean average of the points within a cell and assigns this to the cell. Alternative options are available, including choosing the lowest or highest values among others. The mean average approach produces a smoother effect, as unusually high or low values are averaged out, but can result in cells being assigned values which do not match any of the points they contain and can also average out the archaeological details being sought. If a cell is encountered where no point data exists, a value needs to be generated; this can be an arbitrary value that is assigned to all “no data” cells, or an individual value can be tailored for each “no data” cell. This tailoring is achieved through a process called interpolation. Interpolation is a mathematical process that looks at the known values of the surrounding cells and uses these to generate a new value for the “no data” cell. There are a number of different formulae available to

carry out this process, such as kriging, natural neighbor, spline, and inverse distance weighted (IDW); a full explanation of each method is available elsewhere (Wheatley and Gillings 2002, 183). The advantage of interpolation is that a smooth, natural-looking surface is produced without holes in the data; however, this is achieved by adding fabricated values to the dataset. An additional disadvantage of the rasterization process is that it reduces spatial accuracy, assigning a measured value not to a point but to an area.

Once the raster has been generated, a wide range of different visualization options are available, including hillshade, slope and sky-view factor. These can be employed to visualize the data and allow interrogation of the area for archaeological features (see LIDAR DATA VISUALIZATION AND PROCESSING). Alternatively, the raster can also be statistically analyzed in a geographical information system (GIS) to answer a range of archaeological questions.

Airborne Remote Sensing

DAVID C. COWLEY

Historic Environment Scotland, UK; Ghent University, Belgium

In archaeology, remote sensing (or Earth observation) is an umbrella term for noninvasive and nondestructive approaches that draw on a range of airborne/satellite sensors for collecting information—in particular, for detecting and understanding sites and landscape without making direct physical contact. This suite of sensors may record buried features and those with a surface expression, and are a primary source for exploring the material traces of past activities and their context, further informed by understanding of both data and landscape processes (ancient and contemporary). In some environments, remotely sensed data provide unique information or offer a step-change in the archaeologist's ability to explore, map, and understand the landscape. Remote sensing approaches embody a development from a traditional focus on sites to examination of context, large areas, and broader processes such as mobility or land use.

Sensors can be characterized as either passive (i.e., imaging) or active, and may be mounted on platforms including satellite, aircraft, and unmanned aerial vehicles (UAV). In passive systems, the sensor (e.g., camera) records naturally emitted and/or reflected radiation (e.g., reflected sunlight), whereas in active systems, a signal (e.g., laser light or radio waves) is emitted and the reflectance or backscatter from the target is measured by the sensor. These basic sensor characteristics interact with the Earth's surface either to provide direct measurement of target attributes (e.g., topography) or to record proxies (e.g., spectral characteristics) through which objects of potential interest are represented. Or they may do both, as with airborne laser scanning (ALS) or light detection and ranging (LiDAR) (see AIRBORNE LASER SCANNING AND LIDAR) where, depending on the wavelength in use, the

intensity of the laser return can provide a proxy for soil moisture and other surface characteristics beyond the topography that is expressed as x, y, and z coordinates.

While some aspects of remotely sensed data may be relatively self-explanatory (e.g., contrast and shadows), other datasets (e.g., hyperspectral imaging and ALS) require extensive data processing and manipulation to produce outputs that support mapping and interpretation (see LIDAR DATA VISUALIZATION AND PROCESSING). These include corrections for uneven surface illumination (radiometric distortion) and variation in terrain, and visualization routines. Furthermore, sensor types and the character of the target area interact with factors such as weather, ground conditions, resolution or scale, bandwidth, and lighting direction to impact on the usefulness of products for particular purposes.

Aerial photography and other passive imaging techniques

Airborne observers taking selective oblique photographs of targets deemed of interest are the original form of archaeological remote sensing (see AERIAL PHOTOGRAPHY). More generally, area-coverage photographs have been used, especially declassified military intelligence imagery and government photography. Historical coverage from the mid-twentieth century and earlier can provide unique records of landscapes that have been comprehensively altered since. For small areas, increasing use is being made of UAVs. Beyond recording the Earth's surface, aerial photographs are used to measure the positions of features and derive three-dimensional (3D) data using photogrammetric techniques. This application has grown as powerful structure from motion (SfM) (see STRUCTURE FROM MOTION) software drawing on developments in computer vision has become readily available and revolutionized the production of point clouds, orthophotographs, and 3D models (see DIGITAL PHOTOGRAMMETRY).

While traditional photographs record visible light, other parts of the electromagnetic spectrum, such as infrared (see IR THERMOGRAPHY) and thermal imaging, can reveal additional information. Indeed, near-infrared (NIR) has demonstrated its value for imaging vegetation contrasts, and such documentation is especially effective where the thermal properties of archaeological remains have a high contrast to their surroundings. With hyperspectral and multispectral imaging, information from across the electromagnetic spectrum is collected (see SATELLITE HYPERSPECTRAL AND MULTISPECTRAL IMAGING), extending the opportunities for detecting features of interest, such as varying vegetation condition caused by archaeological objects (Doneus et al. 2014).

Active sensors

Active sensors may emit radio waves (radar) or laser energy (ALS), detecting and measuring the radiation reflected from the target to calculate the distance between sensor and target. Such sensors are generally satellite and aircraft mounted, but are increasingly being scaled down for UAVs. They mainly record surface topography, though the sensors also capture information that can be a proxy for buried remains.

The main benefit of synthetic aperture radar (SAR) (see SYNTHETIC APERTURE RADAR) is in providing digital elevation models of large areas, though development of helicopter-mounted systems may provide higher-resolution data more suited to archaeological purposes. Sensor angle can be quite oblique, and shadows created by features like trees and buildings can be problematic. Data can be very noisy, but in some environments SAR records buried features through limited penetration of the surface, and has some capability to penetrate vegetation.

At present, ALS is more developed as a technique to record high-resolution datasets, with ground point densities greater than 25 points per m² routinely available, and UAV-based systems offering in excess of 2,000 points per m². This is a step-change for prospection in woodland if there are enough ground points to effectively strip away above-ground vegetation and so document

subcanopy surface topography. ALS is valuable for slight topographic features in cultivated ground and earthworks, also providing digital surface models for landscapes. In all cases, the point density has a fundamental impact on what is recorded. ALS reflectance values can provide proxies (e.g., varying soil moisture) for buried features such as river channels. The basic approach of laser scanning has been successfully extended to shallow water, through development of airborne laser bathymetry (ALB) (see UNDERWATER THREE-DIMENSIONAL LASER IMAGING) that can record submerged surfaces (Doneus et al. 2013).

Scale and resolution

The usefulness of data for specific purposes will be conditioned by its spatial, spectral, radiometric, and temporal resolutions, and how these inherently connected attributes interact with the character of targets. Spatial resolution in traditional photographs is an expression of the relationships between flying height, camera focal length, and negative size, with the highest resolution offered by large negatives captured from low altitude. In digital cameras and spectral imaging systems, this translates into the size of a pixel as a unit of the ground surface—and the effective ground area of a pixel may vary from less than 1 m² to tens or hundreds of square meters. In optical systems, the quality of the lens will also have an influence on the nominal resolution. This has a fundamental impact on the size of the features that it is realistic to detect. Taking traditional aerial photographs by way of example, these may be captured at scales varying from 1:5,000 to 1:24,000 and beyond. At 1:5,000, a ground feature 5 m across will measure 1 mm across on the image, while at 1:10,000, the same feature will measure 0.5 mm across, and at smaller scales (e.g., 1:100,000) the feature will be vanishingly small. While issues of scale are easily ignored in digital environments where zooming is simple, they none-the-less have major impacts on applicability.

With ALS and other methods of producing digital topographic data, the principal arbiter of scale is ground point density and the pixel dimensions of the surface models produced by processing. For photographs and other imaging, the spectral resolution is determined by

the wavelength width of the different frequency bands recorded, or in the case of radiometric resolution the different intensities of radiation that the sensor can distinguish. Another aspect of resolution is the frequency with which a target area has been documented, and this temporal resolution is fundamental to diachronic studies and mapping landscape or condition change.

Interpretation and mapping

Some applications of archaeological remote sensing have fixated on site discovery, while the output of other remotely sensed data (e.g., digital surface models) has stalled at a stage of producing pretty pictures in which meaning is assumed to be self-evident. To a degree, this is an inevitable consequence of the introduction of novel methods, in the initial stages of which the focus is on resolving technical issues and exploring the character and potential of the data. However, mature applications of remotely sensed data rapidly move beyond this stage to explore what the data tell us about the past. Users of remotely sensed datasets usually incorporate their outputs in geographical information systems (GIS), where they can be combined with other data and used as a basis for interpretation and mapping. It is here that the challenge of moving beyond anomalies and features should be addressed, driven by data articulation and archaeological interpretation. The identification of objects for mapping has traditionally relied heavily on human observers to identify what is of interest. Developments in computer vision and, increasingly, artificial intelligence are being brought to bear in this process. This recognizes that large datasets demand a computational approach, and should exploit the dynamic tension between what a human observer may identify, drawing on experience and knowledge but also constrained by expectation, and what an algorithm may flag in an entirely systematic and unambiguous approach to pattern recognition (Bennett, Cowley, and De Laet 2014) (see SUPERVISED PATTERN RECOGNITION).

Future directions

Since the beginning of this century, we have seen enormous developments in remote sensing, including dramatic increases in availability and resolution of data, and a proliferation of processing routines. These developments present a challenge to better understanding of how archaeological remains are manifested in such data, and how this influences observation and interpretation. Rapidly changing land-use practice, in some cases driven by climate change, is impacting on the continued contribution to knowledge of some approaches that depend on vegetation responses (e.g., photographic/spectral imaging of crop stress), and this is why prospection tools such as large-area geophysical survey are so important. Understanding strengths and weaknesses of methods and their applicability in specific contexts is crucial, without which unthinking applications may lead to disappointment and poorly understood outputs.

Remotely sensed data are central to addressing global inequalities in availability of heritage information. While some countries have benefited from over a century of archaeological inventORIZATION, elsewhere heritage information may be highly localized or nonexistent. The development of rapid methods of large-area documentation, drawing on heavily automated object extraction routines and data analysis, is crucial to addressing these disparities. Not only do such developments move beyond the limited capabilities of human observers to explore large and complex datasets, but also they should place the processes of identifying objects of potential interest on a more explicit and systematic basis than can be achieved by a reliance on traditional observation alone.

FURTHER READINGS

Archaeological Photography

MATTHEW SCHLITZ

Aboriginal Heritage Tasmania, Australia

Archaeological photography is the visual documentation of cultural landscapes, sites, features, and artifacts either on land or underwater. It is a key pillar of archaeological practice: the method used to record and study the material remains of past human activity. The role of an archaeological photographer is to systematically record cultural landscapes or artifacts; document sites prior to, during, and after excavation; record heritage features and standing structures; photograph the spatial association between artifacts; record archaeological methods for lectures and publications; and archive the archaeological record.

Archaeologists have a responsibility to create a technical and illustrative photographic archive for future generations and often under varying circumstances. The archaeological photographer is challenged by temperature, wind and dust, moisture, difficult terrain, vegetation, and commercial time frames. Typical challenges could be determining which artifacts should be photographed in an assemblage of thousands of objects, dealing with high-contrast site photography, or flash photography of a confined cave excavation. The archaeological photographer must assess what site perspectives or artifact detail should be recorded. The photographer is required to apply different lighting methods and perspectives to a variety of heritage—site features, ceramics, stone artifacts, coins, glass, bone, shell, metal, wood, and textiles. Archaeological images form a scientific, evidential record and should be illuminated correctly, well focused, suitably exposed, and free from distortion. Accurate color representation and the use of a proportionate contrasting metric scale or indicative human figure are important considerations.

From the outset, archaeologists recognized the potential of photography to permanently

record scientific endeavors. Photography enabled a global dissemination of new knowledge of past societies. From large-format cameras and glass plates to single lens reflex (SLR) to drone cameras, archaeologists have constantly sought to use new technologies to capture and document heritage. Given the imperative to systematically document during artifact conservation and excavation—inherently a destructive process—archaeological photography was an ideal, complementary alternative to the drawn record. Maurice Cookson (1954) typified a rigorous, systematic approach to photographic recording and became a key figure in the development of archaeological photography in post-World War II Britain. Technical aspects of archaeological photography were later explored by Harp (1975), the *Deutsches Archäologisches Institut*, and further championed by Dorrell (1996) whose *Photography in Archaeology and Conservation* has become a seminal technical work on the subject. In the tradition of Cookson and Dorrell, the Institute of Archaeology continues to offer archaeological photography as a formal stand-alone subject. Unfortunately, this is still a rare offering at universities globally.

Recent literature on archaeological photography has focused on three-dimensional (3D) case studies rather than on international standards or new approaches to artifact photography. There has been relatively little academic discussion over the last decade concerning standards in archaeological photography, metadata, photography of artifact assemblages, small artifact scanning, and streamlining artifact photography workflows and project archives using digital asset management (DAM). There is potential for greater standardization, including international scales, approaches to technical documentation of artifact types and assemblages, and a greater emphasis on university technical training and accreditation—critical given the exponential increase in digital output. Archaeological images should equal or surpass those of the past.

The relationship between photography and archaeology has come under closer inspection, with an examination of the way the past is

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

DOI: 10.1002/9781119188230.saseas0028

perceived and the objectivity and subjectivity of cultural images. Visual anthropologists have critiqued the “objective” representations of reality in archaeology to argue for an artistic, even subjective role of the cultural image. Personal camcorders are now used during excavation to personalize archaeological research and demystify the objective nature of archaeological method.

Aerial photography and satellite imagery are extremely useful prospection and analytical tools and have provided a key site and landscape perspective since the advent of the first camera in the 1840s. Low-level aerial archaeology platforms including kites, balloons, and photographic booms enable archaeologists to obtain aesthetic vertical and oblique site images. Given the development of unmanned aerial vehicles (UAVs) by the military, it was inevitable that low-cost drone systems would become available to and adopted by archaeologists.

Scientific photographers employ infrared, near-infrared, ultraviolet (UV), and multispectral imaging techniques to highlight archaeological details difficult to detect in the visible light (Dorrell 1996). Visible light, UV reflectance, UV fluorescence, and infrared photography can be employed to detect chemical signatures indicative of textile colorants (Baldia and Jakes 2007). Other artifacts suitable for multispectral imaging include painted wood, canvas, leather, and the ink on parchment, such as revealed in biblical inscriptions. Fluorescence photography can distinguish the presence of organic and mineral elements in wall-paintings and textiles, and xeroradiography can assist conservators in the restoration of metal artifacts. Archaeologists exploring confined spaces utilize endoscope photography. Scanning electron microscopy (SEM) is a key imaging tool to identify residues and use wear. Laser scanning confocal microscopy (LSCM) and 3D focus variation microscopy (FVM) are being used for use-wear analysis in lithics research.

The greatest change in archaeological photography has been the exponential increase in photographic resolution and uptake of camera hardware, the obsolescence of film emulsion, laser scanning, and drone technology. Given the time, effort, and cost involved in producing archaeological images, high-quality archival records

should be standard. Historically, large-format or medium-format cameras with digital backs were the ideal due to the level of detail extracted from the negative. Archaeologists are closer to this ideal, with 30- to 50-megabyte digital single lens reflex (DSLR) cameras approaching parity with medium-format resolution. The explosion of mid- to high-resolution mobile phone cameras also has provided archaeologists with a snapshot record, albeit with limitations. Handheld, ultra-portable 3D laser scanning cameras may eventually be manufactured to provide greater manipulation of stone artifact conjoins, mosaics, architectural elements, glass, and pottery.

Recent developments in archaeological photography and computational photography include the application of multiple light imaging or polynomial texture mapping (PTM) to site features and artifacts (Duffy et al. 2013). A two-dimensional (2D) process, PTM relies on multiple sources of light from different angles to define variation in the surface of the object or feature. Structure from motion (SfM) is a photogrammetric range imaging technique that enables archaeologists to produce 3D structures from 2D image sequences. High-resolution digital imaging enables the archaeologist to speed up the documentation of endangered sites due to erosion, development, and conflict (CyArk project). Laser scanning allows archaeologists to create virtual monuments and interiors, document excavation stages, and illustrate sites for virtual reality (VR) experiences. Laser scanning and computer-numerical-controlled (CNC) design or large-scale 3D printing could be used to replicate small artifacts or even replace destroyed or stolen elements of buildings.

Computer enhancement of rock art has been utilized for decades to shed light on difficult-to-detect images or recover previously recorded art images. The results can provide additional opportunities for relative dating and a potentially vast corpus of new rock art. Jon Harman developed D-Stretch, a low-cost app to enable the reevaluation of rock art. Advances in mobile computing enable archaeologists to illustrate directly onto rock art imagery and minimize the impact of tracing directly onto the rock art surface.

Digital imaging has provided greater opportunities for archaeologists to store, retrieve, and

disseminate research via image databases or the cloud. The challenge is to ensure authenticity of the original digital image and manage archaeological image workflows when utilizing open source digital asset management (DAM) software. It is foreseeable that medium-format resolution will be available in the size of compact camera and that portable 3D scanning cameras, inbuilt camera scales, and/or metadata inputs linked to DAM workflows are likely to become standard. Archaeological photography is now firmly in the realm of both high-resolution 2D recording and a complementary, immersive 3D, aerial, or VR experience.

Augmented Reality

STUART EVE

University of Leicester, UK

Augmented reality (AR) is part of the wider concept known as mixed reality (MR). MR is generally accepted as a way to seamlessly combine our perception of the real world with digital or created elements. It is best defined by a scale known as the reality–virtuality continuum first proposed by Milgram et al. (1995).

As can be seen in Figure 1, the scale goes from the real environment (RE) through AR and augmented virtuality (AV), to a full virtual environment (VE). The full VE can be thought of as virtual reality (VR). The term virtual reality (see VIRTUAL REALITY MODELING) has now been accepted into modern everyday language, and has been defined as the computer-generated simulation of a three-dimensional (3D) image or environment that can be interacted with in a seemingly real or physical way by a person using special electronic equipment, such as a helmet with a screen inside or gloves fitted with sensors. VR involves the entire creation of a world within a digital environment; AR, on the other hand, involves the limited creation of digital elements, which are then combined with the real world.

AR therefore allows a user to work in a real-world environment while visually receiving additional computer-generated or modeled information to support the task at hand. There are a wide number of applications of this technology: interactive greetings cards, advertising of various products, visualization of computer-generated geographic information systems (GIS) data overlaid onto actual locations (Ghadirian and Bishop 2008), and indoor and outdoor gaming; even heads-up displays (HUDs) in modern aircraft are a form of AR—overlying information from the aircraft's systems and projecting them onto the pilot's display.

Visual AR can be deployed using three main methods: a head-mounted display (HMD), a smartphone or tablet, and projection mapping.

- *Head-mounted display (HMD)*: HMD involves the user attaching a device to

their head that mediates what they see; the device can overlay information directly onto a see-through screen, meaning the user is seeing the real world through their own eyes (an optical see-through device, for example Microsoft HoloLens) or through a completely closed system, where the information fed to the eyes is via one or more video screens bringing information from cameras on the outside of the device (a video see-through device, for example Google Daydream).

- *Smartphone/tablet*: By using the built-in sensors (global positioning system (GPS), compass, accelerometer, camera, etc.) of a tablet or smartphone this can provide a relatively low-cost and accessible approach to AR. Typically in this case, the video feed from the on-board camera is augmented with virtual information as the user moves around. This is the most common use of AR, and is quickly becoming popularized through the use of location-based gaming such as Pokémon Go, and social media applications such as Snapchat. AR using user-held or worn devices can be triggered in two main ways: location-based AR and marker-based AR.
 - *Location-based AR*: One of the over-riding concerns when deploying an AR experience is to ensure that the digital content is delivered to the user with the correct perspective and scale and is registered correctly with the real world. For the digital content to be placed accurately in relation to the user, the AR delivery device needs either to have knowledge of the user's current location (via GPS and digital compass) or to be able to interpret what the user is seeing in real-time (via a 3D depth camera), or a combination of the two. Within archaeological contexts, location-based AR is used most often in location-aware audio-guides; for showing directions to different archaeological features in the field; or for providing other contextual media (such as videos or photographs) in situ.
 - *Marker-based AR*: As opposed to location-based AR, marker-based AR relies almost solely on computer vision algorithms to accurately place the virtual content within the delivery device. A

Figure 1 RV scale.

physical, printed marker (such as a poster or interpretation panel) is placed within the real world and, when it is viewed by the AR application, the marker is replaced with digital content. This is often used in museum exhibitions or to augment site signage with extra information.

- *Projection mapping*: Rather than making use of user-held or worn devices, it is possible to project the augmented information directly into the physical space. This method is currently most often used to project images, videos, or animations onto building facades using commercial-grade projectors. The software uses a virtual 3D model to calculate the projection parameters, meaning it is possible to make the projections appear to bend around the building or surface itself. Projection mapping can be used on historic building facades to display the previous phases of a building, or in museum contexts to create interactive exhibits.

Existing example uses of AR in archaeology

One of the earliest applications that used AR for archaeological interpretation is the visual interaction tool for archaeology (VITA) introduced in 2004 by researchers at Columbia University (Benko, Ishak, and Feiner 2004). VITA uses an AR interface to aid in post-excavation analysis of the site of Monte Polizzo. VITA presents a system that allows multimodal engagement with the archaeological data—through use of a head-worn display, a multi-touch projected table surface, speech commands, and a tracked glove. As well as the “world in miniature” mode, where a small-scale virtual model of the excavations is

displayed on the physical table-top in the office, VITA provides a “life-size-world” mode, which shows the textured and meshed model of the excavation at 1:1 scale within the user’s head-worn display. The user’s location is tracked and therefore they can walk “around” the excavation site. By using the tracked glove, users can examine the archaeological finds at their exact locations of discovery within the 3D model. VITA also combines a number of different mechanisms to deal with the various different types of data (two-dimensional (2D), 3D, high-resolution, etc.) which ensures the data are always shown in the most appropriate way; for example, a Harris Matrix is viewed on a 2D display, whereas the 3D model is experienced using the head-worn display.

Applications such as ARCHEOGUIDE (Archeoguide 2010) move the AR experience out of the computer laboratory and into the site itself. ARCHEOGUIDE, released in 2001, is an early example of using an AR device to aid in a tourist’s experience of an archaeological site. When the tour begins, each user is asked to generate a profile outlining what their interests and background are; a personalized tour is then created for that user to follow. The user is given an AR HMD, and reconstructions of the ancient buildings are overlaid directly onto the real world as they walk around the site. George Papagiannakis and Nadia Magnenat-Thalmann (2007) produced one of the best-known heritage AR applications, centered on the site of Pompeii. Using a tracked video-see-through HMD and dynamic modeling of the real and virtual world, Papagiannakis and his team were able to insert virtual characters into various buildings within Pompeii and enact a real-time storytelling scenario, using dynamic occlusion of the virtual objects by both the virtual characters and real visitors. The speech engine in Papagiannakis’s work also allows interaction from

the user—creating a feeling of social interaction with the virtual characters.

Multisensory and multimodal AR

The majority of AR experiences currently concentrate on *visually* augmenting data; however, it should be noted that the other senses can also be augmented: for instance, the use of headphones (such as in an audio guide) or smells introduced into an environment (such as York's Jorvik Centre). The author in his work on the embodied GIS (Eve 2014) uses AR as an exploratory tool, augmenting the results of spatial statistical analysis onto the in-situ landscape of Bodmin Moor, United Kingdom. In addition he makes use of multisensory AR to augment the smells and sounds of the ancient landscape, to enable archaeologists to test hypotheses and change parameters as they are exploring the space. Each sense is augmented in different ways, and some are currently easier than others. For instance, visual and auditory AR can be achieved by HMDs or headphones, but smell, touch, and taste require more sophisticated interfaces—most of which have not yet been used to full effect in archaeological contexts. It should be noted that some of the more successful AR applications (most commonly in a museum context) use a combination of AR interfaces (multimodal) to deliver the experience, adding to the feeling of presence or immersion in the AR content.

Continuing use of AR in archaeology

Currently, AR is in limited use in archaeology. The reasons for this are a combination of the need for specialist programming skills, the cost of the hardware and development of the applications, and the lack of mass adoption of the technology. As with many new technologies, this situation is fluid, and in the coming years both AR and VR technology is due to be widely adopted, with some industry analysts predicting a paradigm shift away from using monitors and keyboards to using HMDs with context- and location-aware content for our primary interaction with computers. As the technology becomes more widespread, there are

clear avenues for the use of AR in archaeology. The main drive currently is for use in education and tourism for museum displays and also for presenting archaeological information to the public on heritage sites, in situ. We can expect this remit to expand in countless different ways, some examples of which may be:

- AR being used to aid in artifact identification (for example, recognizing and recording animal bone species);
- conservation (virtually marking repairs on structures or objects and using an AR viewer to see them);
- augmentation of museum or heritage site literature;
- augmentation of 3D-captured artifacts into public and private spaces (for example, a virtual Greek urn sitting on your shelf at home);
- ongoing archaeological excavations being captured digitally and then displayed in situ after the trenches are closed.

AR can also facilitate the creation of “what-if” scenarios, by providing a platform to create various theoretical models of site-use which could then be tested from a body-centered perspective. For instance, what would a certain landscape have looked like if it was covered with trees? How would the shape of a house change in the landscape if it had a porch or windows? What if the ground level was lowered or the course of a river changed? What if there were other semitemporary buildings built into a settlement, which may have not survived in the archaeological record? What would the landscape look like in varying different weather conditions (bright sun, fog, snow, heavy rain, etc.), and how would this affect the views to and from a specific monument? It is possible to remove modern intrusions in a landscape using AR technology (sometimes called diminished reality), allowing a site manager to virtually remove modern buildings or infrastructure to give an impression of the past landscape.

AR technology is still at an early stage, and while some sophisticated applications can be currently built, the technology is only going to improve, and the future holds many exciting

prospects. AR, working in tandem with advances in 3D reconstruction, means we can now undertake body-centered journeys through our data that were previously in the realm of science fiction and that will now open up new insights and discoveries of our shared past and allow archaeologists and tourists alike to experience the sites and artifacts in new ways.

Authenticity in VRM

JOYCE WITTUR

Independent Scholar, Pfungstadt, Germany

Authenticity is a very ambivalent term; it can have different connotations depending on discipline, cultural background, and the individual speaker. It is therefore necessary to explore its meanings before its relevance to virtual reality modeling (see VIRTUAL REALITY MODELING) (VRM) can be assessed.

The roots of the word lie in Greek *authéntēs* (*aut* meaning self and *hentēs* meaning doer), that is, the “originator” but also the “murderer.” The term authentic was first used in regard to texts. In medieval Latin, *authenticum* describes an original manuscript, which was written by the person to whom it is attributed, thus differentiating it from the “inauthentic” texts whose authorship is unknown or unverified. The use of the word has nowadays spread well beyond the confines of historical texts and is used in a great number of contexts with a variety of concepts in its wake, ranging from “personal authenticity,” as established by Jean-Jacques Rousseau, to the authenticity of museum exhibits (Saupe 2017).

The concept of authenticity is best defined by looking at its opposite principles. Staying for the moment with the example of the museum exhibits, this would be the forgery, the replica, and the derivative work. The forgery claims to be something that it is not. It aspires through form, material, and other traits to persuade the observer to experience it as a genuine representative of its kind, with the outspoken intent to mislead. Here, the semblance of authenticity is the prime aim; if it can be achieved, then the forgery is successful.

A replica, on the other hand, can be worked just as skillfully as a forgery, but it does not want to deceive the observer regarding its genuineness. Replicas can be useful when originals are unavailable or too fragile for exhibition or even research (e.g., hominin fossils). They do not initially claim authenticity, but they can acquire it if the original

is lost or they are valued as works of art in their own right.

The latter can also be true for derivative work. It depends on whether the product is perceived as enough of a work of art—as in appropriation art—or as a mere copy, whereby the author of the work and the quality of execution, for example, a cheap souvenir, can have a great influence on said perception, and with that on the authenticity of the object.

From this it becomes apparent that two kinds of authenticity are at work: one inherent to the artifact, the other based on (public) discourse. For museum exhibits, the questions appear to be: are they genuine, are they original, are they art? But looking at other disciplines and objects, a much wider range of criteria may be applicable. In heritage preservation, the concept of authenticity has undergone a marked change over the last decades. At the beginning of the twentieth century, authenticity was felt to be located in the extant remains of monuments, whereby it was debatable whether later additions or changes to these monuments also held authenticity or not. In the Test of Authenticity (§9) of 1977 (UNESCO 1977) “design, materials, workmanship and setting” were seen as essential, whereby subsequent additions or changes were also included. That this reflects a rather western, in contrast to a global, approach to authenticity was recognized in subsequent years, leading up to the Nara Document (UNESCO 1994). In §13, the scope of authenticity was significantly widened in order to incorporate non-western concepts. The criteria for authenticity now included “form and design, materials and substance, use and function, traditions and techniques, location and setting, and spirit and feeling, and other internal and external factors.” Including tangible as well as intangible values in the test of authenticity is an appropriate response, especially when dealing with monuments, which undergo continuous alterations—be it for spiritual reasons or from a conservational standpoint. Despite these changes, it can still be argued that authenticity remains a more or less western concept.

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

© 2018 John Wiley & Sons, Inc. Published 2018 by John Wiley & Sons, Inc.

DOI: 10.1002/9781119188230.saseas0055

The use of the word *authentic* in the realm of living history (and in part in experimental archaeology (see *EXPERIMENT IN ARCHAEOLOGY*)) encompasses a similarly broad spectrum. Raw materials, modes of work, or designs as gleaned from archaeological finds, together with other characteristics, are often termed *authentic*, leading to contradictory concepts like “*authentic replicas*” (Samida 2014). The strive for authenticity in living history also encompasses the yearning for authentic emotions.

Not only staged events but also memorial places or historical sites vie for our emotions. It is often argued that it is the aura of a place, its material authenticity, that makes us respond to it. On the other hand, the auratic experience could well be a self-fulfilling prophecy: the claim that a place or an object is authentic and this authenticity lies within its fabric makes us experience it thus (Fitzenreiter 2014). This means that authenticity can be assigned. A pact of authenticity is forged between the visitors and the experts or institutions responsible for the exhibitions in museums and historical sites and it holds as long as the social and cultural context is stable (Saupe 2017). The presentation of the artifacts is staged: they are taken out of their context, artificially illuminated, and presented as something extraordinary. By accepting this view and emotionally responding to it, the observer is agreeing to the pact. Nevertheless, it is not only the artifact that benefits from authentication, but also the authenticator who legitimates his own expertise through the act (Bendix 1997, 7). Accepting that authenticity is a construct, it follows that authenticity can also be deconstructed, for example, when a forgery is exposed.

There has been some doubt whether authenticity (when seen as a construct by experts, institutions, and the general discourse) is actually a useful or even valid concept for the social sciences, especially if it is more or less arbitrarily used to separate what is worth studying, preserving, or exhibiting from what is not (Bendix 1997, 4–9; Seidenspinner 2008, 282).

However, a persistent desire for authenticity can be traced from the mid-eighteenth century up to the postmodern era, in which people long for the real and the true in a world, which is perceived to be full of surrogates and fakes (Seidenspinner 2008, 282).

After considering these in part conflicting definitions of authenticity, it is time to consider how virtual reality models fit into the picture. The models can be constructed in a number of ways; for example, they can be acquired via laser scanner (see *LASER SCANNING*) or they can be modeled by digitizing old paper plans and drawings by hand. The important part is that they are always *constructed*, which means that at some point in their making, subjective decisions have to be taken. No amount of detail can counter the fact that the virtual model is not the real object, but often enough just a hull, which replicates the outer appearance of the modeled artifact. There are methods to capture the interior of an artifact too—a computed tomography (see *COMPUTED TOMOGRAPHY*) (CT) scan may be a case in point—but there are still the questions of resolution and interpretation (see *INTERPRETATION*) of the data obtained from the scan. Therefore, the resulting models are not objective, and interpretations are usually considered to be inauthentic.

Even when looking at certain aspects of VRM—in accordance with the criteria for heritage preservation—namely materials and substance, traditions and techniques, location and setting, use and function, spirit and feeling, and form and design, we find the virtual models lacking. Most obviously, this pertains to materials and substance because we are dealing with virtual and not real artifacts. Traditions and techniques seem similarly inapplicable: the “tradition” of creating virtual models only reaches back to the early 1980s, and the techniques to generate them are ever changing with the advancement of technology. Virtual models, for instance, in the form of augmented reality (see *AUGMENTED REALITY*), can be georeferenced and projected onto a physical site, so that they seem to be located in their “authentic” setting. Nevertheless, this is an illusion, because the model is in itself not bound to a specific place. It is also possible to simulate the use of a virtual model, for example, the workings of a pump, but the way in which we interact with the model is far removed from using a real pump or its functionality of drawing water. Models can evoke feelings, and they can be awe-inspiring and moving, as well as creating a great range of other emotions. This kind of emotional response is often due to staging, for

instance, the play of simulated sunlight through virtual stained glass windows; it is a calculated product conjured up by the makers of the model and not due to its “authenticity.” Additionally, (so far) no real embodiment (see BODIES AND EMBODIMENT) can be achieved, which is vital for experiencing a place with all the senses and giving the *impression* of really being present. Finally, form and design have to be considered. The VRM can delineate the shape of an original artifact in great detail, but what the computer stores is not a real form; instead it deals with coordinates in space and/or mathematical functions which appropriate the form but are not the form in itself. It is possible to create a tangible object from the data, for example, via 3D printing (see THREE-DIMENSIONAL (3D) PRINTING AND ADDITIVE MANUFACTURING); nevertheless, this object would be a mere replica and therefore hold no authenticity. The case may be argued slightly differently for the design of an artifact, if design is considered to be the *idea* behind a shape—like an artist’s vision seen in contrast to the resultant work of art. The intangible vision can take shape in a number of ways, for instance in drawings, physical models, and not least the artifact itself. It could also be represented in a virtual model, as is nowadays frequently the case in architectural planning. In this instance, the model could claim authenticity.

If we accept that authenticity is not an inherent property of an artifact, but something that is assigned by experts, institutions, and the general public, then virtual reality models can also be authentic. In this case, the authenticity would be attributed to the model itself and would not be derived from the original artifact, which has been captured. For this to happen, the model would have to be accepted as an original work, need to be culturally embedded, and be viewed as a product of its time.

Computational Photography

JAMES MILES

Archaeovision, UK and Estonia

Modern imaging solutions through hardware and software parameters make capturing color, texture, and shape more achievable, and allow for data to be presented in a meaningful way. Computational photography, through a combination of several sensing and algorithmic techniques, extends the options available within digital photography. The resultant data provide an image similar to those captured through standard photography, but one that would not have been possible with a traditional camera. Within archaeology, the use of these different computational techniques depends on the research question asked, but can be broadly categorized as providing image enhancement and restoration, image manipulation through warping and mosaicing, and dynamic range map editing. It should be noted that software and computing power is an essential element of computational photography; without specified software we would be unable to produce and manipulate the data that are produced. The majority of software packages require a graphics system that is able to produce these data. With the ever-increasing file size and pixel resolution of modern digital cameras, the need for more powerful graphic interfaces is essential.

The process of capturing computational photographs is not restricted to a digital photographic camera but can be applied to all aspects of digital medium, including X-ray tomography (see *X-RAY TOMOGRAPHY*) and computed tomography (see *COMPUTED TOMOGRAPHY*) via volumetric image analysis. The development of computational photography is based on the application of digital photography which follows the same techniques used in film-based photography, through a shutter optical device. Digital cameras provide readings of the intensity and color via

light-sensitive receptors known as photosites to each pixel of the image (Corke 2011, 229). The pixel information generated contains color wavelengths through red, blue and green filters to create the interpolated final image. Through their capture, sharpening algorithms are used to emphasize edges; image colors and contrasts are balanced; and the data are compressed to provide a suitable storage system (Adams et al. 2012, 124–126). Computational photography is engrained in the image-capturing process and is not simply completed through post-editing alone. The digital cameras that are currently available no longer take a picture, but instead create one.

The capture of photographs relies on the control of the shutter speed and aperture used. Using too wide an aperture provides light but reduces the depth of field; a narrow aperture gives this depth of field but limits the light available. In archaeology the ambient conditions are hard to control and manage: we are reliant on computational methods to correct these issues through post-editing. A number of different processes can be used, but the general application of computational photography can be seen in image correction through the control of white balance, color, and exposure values. Images are normally captured in a RAW format and are controlled via the operating system of the camera used; these RAW formats contain extensive sources of information due to their uncompressed nature. Errors in light, focus, and motion blur can be corrected through post-editing and the images are converted to suitable compressed file formats, such as JPEG, TIFF, or PNG. These images can be further compressed through a system of pyramid imaging. Pyramid imaging provides multiscale representations whereby they are subjected to smoothing and subsampling, creating a system that allows viewers to use the data based on the computational power available (Burt 2013). This is useful when working with large datasets and can be completed via Gaussian or Laplacian algorithms. Pyramid imaging is beneficial when dealing with large datasets through online

DOI: 10.1002/9781119188230.saseas0106

viewing systems such as IIPImage, as the method allows for examination without the need for direct access to data-intensive files.

The basic elements of photographs can be changed through the computational processes outlined above, but a greater number of resources are available, which can aid archaeological work and vary depending on the purpose of the work necessary. The more advanced computational methods are normally in the form of high dynamic range and tone mapping processes; multiperspective and panoramic stitching; light field imaging; and photorealistic and nonphotorealistic rendering. Photographs captured under normal lighting conditions struggle to show both light and dark areas, with one needing to be overexposed and the other underexposed. High dynamic range (HDR) offers greater control over these exposure values by capturing different levels of exposure. Capturing bracketed images at different steps of exposure allows for the creation of seamless images whereby the different dynamic ranges of luminosity can be combined to bring details out in both the shadows and highlights (Wheatley 2011, 258). This is useful when capturing dark areas such as excavation trenches that contain shadows, or interiors that have external lighting. The ability to control the dynamic range within these images creates a system that is more factual; some digital cameras now implement HDR directly within the capturing process, but the results are better represented through software-based modifications.

Multiperspective and panoramic stitching provides a solution to combine a number of different photos as one representative view. The method relies on a mosaicing photographic capture, where a number of zoomed-in images of an object, site, or landscape are taken and then combined to create a unified image (Gledhill et al. 2003, 436–438). Multiperspective panoramas provide an opportunity to view an archaeological site or object as one complete image which removes issues of perspective and are used extensively within cartography to process aerial images (see AERIAL PHOTOGRAPHY). The process involves capturing a number of overlapping images that are fixed on a single plane. Unlike structure from motion (see STRUCTURE FROM MOTION), angled images are not necessary

to create a result; rather the process relies on a stereophotogrammetry process to create a final dataset that represents an undistorted area. This is beneficial when capturing data that are wide or have data blocking specific elements. Panoramic imaging, however, is generally completed from a single point and combines a series of photographs taken with a sideways and up and down movement. The resultant panoramic dataset generally contains some form of error through the perspective present from the single point of view, but this is countered through the different projection settings available. Different projections are available depending on the use of the images; for landscape-based images, for online distribution in systems such as Google Earth, distortion can be included to produce a complete virtual view and experience. If the data are to be used for metric survey or diagnostic exercises, little to no distortion is required. Through orthographic projections, all levels of distortion are removed and the final image allows for a whole view of a given object, site, or landscape. This is completed through morphing and warping the original images to centrally fit the necessary view; through this manipulation, errors may be present on the extremities of the data. The capture process is important in producing orthographic content, as if the viewpoint is not central, or the surrounding images are not captured, it can limit the extents that can be used. These data can now be shared online, making extremely high pixel images available to those that cannot access the areas, creating greater resources to work from.

Light exists and is identified through the electromagnetic spectrum. What we can identify through our eyesight is known as visible light. The electromagnetic spectrum contains radio waves, microwaves, infrared (IR), visible light, ultraviolet (UV), X-rays, and gamma-rays. Through different camera systems and technology these data can be recorded for use within archaeology and are processed through computational means. Typically, the data that are used within archaeology incorporate IR, UV, and X-ray wavelengths. These provide different systems and tools of identification, with chemical analysis, layering, and thermal and internal properties being available. The different wavelengths are processed as computational images that are modified to fit within

our visible spectral range through a number of different processing options. Attached to differing light wavelengths is the manipulation of visible light color bands such as DStretch (Harman 2005). DStretch works through a decorrelation stretch of an image hue modifying color spaces in specific and controlled ways through defined algorithms; the method is of great use within rock art analysis and allows for nearly invisible details to be enhanced.

The use of computational photography ties in with virtual reality modeling (see VIRTUAL REALITY MODELING) through the production of photorealistic models. The details shown are completed through a series of computational methods that involve the direct manipulation of photographs and textural detail. These provide realistic representations of the past through simplified models and are used greatly within virtual reality. The textures present are processed using computational photography software and then mapped to set features. Each element and face of a model relies on these textures to present the data; without this process, the models created would be represented as simple shaded objects that are unrepresentative of the data shown. Connected to the photorealistic element of virtual reality are the computational processes of nonphotorealistic rendering. This technique provides final images that are similar to drawings, diagrams, or paintings. They are produced through an automatic process where features are detected and emphasized to give simple three-dimensional structures that are defined by edges. Color is sometimes confusing and archaeologists rely on simplified drawings to represent the data shown (computer-aided design (CAD) drawings). Through nonphotorealistic rendering, the method provides a system that removes textural data and is useful within archaeology to highlight areas of importance, or to identify features that may not be as prominent. These can be controlled and processed through a number of different software programs, which offer varying degrees of user control over the data produced.

Although computational photography can be utilized within standard imaging, the method has developed into one that provides three-dimensional spatial data. Systems such as photogrammetry (see PHOTOGRAMMETRY AND

STEREOPHOTOGRAMMETRY), and its digital counterpart, structure from motion (see STRUCTURE FROM MOTION), take these two-dimensional images and process them through a number of different algorithms to create virtual replicas. Photogrammetry has existed since the early days of cartography, but with the application of digital photographs and computational methods, the method now provides a routine means to create usable metric data. As the data are digital they can be manipulated and depth values can be extracted. With the increase in photogrammetric software and image resolution, the results produced can be seen to be similar to laser scanning (see LASER SCANNING) and provide an economical tool for conservation and archaeological recording. Similarly, the image processing, through computed tomography, which is completed via several layered, angled X-ray images, enables a recording method that can identify internal properties. Computational photography is no longer restricted to two-dimensional representations, but now enables novel and metric examinations of archaeologically important artifacts (Miles et al. 2016).

Computational photography can also be utilized to analyze surface details of objects, namely through the reflectance transformation imaging (RTI). The application of taking multiple images with varying light positions enables a two-and-a-half-dimensional examination, where the normal variance of the images is inspected. RTI, through various rendering modes, allows for details to be shown that cannot be seen with the naked eye. The process involves the movement of a virtual light within specific software to introduce shadowing. The method highlights the importance that digital imaging has and how computational photography can increase the results shown. There has been an increase in the use of RTI within archaeological research, involving IR, UV, gigapixel, virtual, and underwater-capture procedures; using standard photography, such results are not possible (Archaeological Computing Research Group 2016).

Computational photography is not just one method; it is a combination of many different computational processes that are used within archaeology. The methods discussed have highlighted a small number of possible processes

available with computer vision and have demonstrated how computer scientists are creating new forms of tools to analyze the past. The method in its basic function provides a means to manipulate the original captured data, but it can be used at varying levels to enhance details in the archaeological record, from simple exposure settings, to dynamic range variations, through to the production of three-dimensional metric data.

Computed Tomography

STEPHEN HUGHES

Queensland University of Technology, Australia

X-ray analysis is used extensively in analyzing archaeological artifacts (see X-RADIOGRAPHY AND CERAMICS; X-RAY RADIOGRAPHY AND MATERIAL ANALYSIS; X-RAY ABSORPTION SPECTROSCOPY (XAS, EXAFS, XANES); X-RAY PHOTOELECTRON SPECTROSCOPY (XPS); X-RAY RADIOGRAPHY; X-RAY TOMOGRAPHY; XRD AND MATERIALS ANALYSIS; and X-RAY FLUORESCENCE SPECTROMETRY (XRF)). X-ray computed tomography (X-ray CT) is a means of seeing inside objects and materials without the need for any destructive intervention. CT scanners are mostly used in medicine, where cross-sectional X-ray images and three-dimensional (3D) reconstructions are used to look inside a patient without the need for exploratory surgery. However, CT is also used extensively in archaeology, where the X-ray images can reveal details of the internal structure and composition of historic artifacts. An issue with the use of X-rays in medicine is that X-rays are ionizing; that is, they have enough energy to eject electrons from atoms, causing damaging chemical reactions in cells. Clearly, in archaeology the adverse biological effects of X-rays are not an issue. The analysis of inanimate objects using X-rays is a form of nondestructive testing.

The word *tomography* is derived from two Greek words—*tomo* and *graphia*. *Tomo* means to cut—as in a *microtome* that cuts slithers of material for examination under a microscope. *Graphia* means to write or draw—so, putting these two words together, a tomogram is a cross-sectional image of an object. For example, a tomogram is able to reveal details within an object unobtainable from an ordinary flat or plain X-ray. In a plain X-ray, it is known that the heart and lungs are inside the ribcage. However, if the ribcage contained a foreign object, the depth of the object beneath the surface would not be apparent. In the case of a plain X-ray of an Egyptian mummy,

for example, it might not be obvious whether an amulet is inside or outside the bandages wrapped around the mummy. An X-ray CT scan will easily show which is the case.

Another major advantage of CT scans over plain X-rays is the dramatic improvement in contrast. Image contrast is a measure of the difference between dark and light areas in an image. The greater the contrast, the easier it is to visually differentiate features. To give an everyday example, it is easier to see objects in bright rather than dim light. A subtle feature might be invisible on a plain X-ray due to lack of contrast with the surroundings but seen clearly on a CT scan.

How are X-ray CT scans produced? Before answering this question, we need to step back and consider the nature of X-rays. X-rays are part of the *electromagnetic spectrum*. X-rays are essentially the same as light rays, microwaves, and radio waves. The only difference is that X-rays have a much shorter wavelength than the former. The shortness of the wavelength means they have greater energy. In an X-ray machine, X-rays are produced by bombarding a tungsten target with high-speed electrons. Electrons are produced by running an electric current through a thin wire called a filament until it glows with an orange heat. This 'boils' off electrons, which are accelerated towards the target using a high voltage (about 125,000 volts in the case of an X-ray CT machine). The high voltage acts like a catapult on the electrons.

The electrons race towards the target at over half the speed of light and when they enter the target they interact with atomic nuclei and produce X-rays. As the high-speed electrons career around the nucleus of an atom, like a racing car on the curved section of a race track, they emit X-rays at a certain angle to the direction of travel—the angle being dependent on the energy of the electrons. As the electrons curve around the nucleus, kinetic energy is converted into X-rays and as a result the electrons slow. However, the process is very inefficient—only about 1 percent of the kinetic energy of the electrons is converted into X-rays; the rest is heat. In practice, the X-rays

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

DOI: 10.1002/9781119188230.saseas0107

come from a small point on the target and travel at the speed of light to the object being imaged.

When X-rays enter an object, they interact with atomic electrons and are removed from the primary beam. As X-rays penetrate deeper into matter, they are progressively removed from the primary beam through scattering. In other words, the intensity of the beam reduces. This is a bit like throwing a hundred tennis balls into a forest. If we were to go into the forest and measure the distance of each ball from the edge, we would discover that the number of balls would decrease with distance. So it is with X-rays entering an object. The intensity of an X-ray beam entering an object reduces exponentially; that is, the intensity

of the beam is reduced by a constant fraction for each unit depth of penetration.

The X-rays that make it all the way through the object impinge on a detector—in the past film, but nowadays electronic—similar to the detector in a digital camera except with a sheet of material in front of the electronic sensor to convert X-rays into flashes of light—a process known as *scintillation*. If the X-rays have passed through a denser region of a given object, more will be absorbed and fewer X-ray photons will reach the detector. In essence, the denser regions of an object create X-ray shadows.

In an X-ray CT scanner, several plain X-rays are taken from different positions around the

Figure 1 (a) Schematic diagram showing the principles of back projection using a fan X-ray beam projected through an object. (b) Lateral plain X-ray of an ancient Egyptian mummy. (c) Cross-sectional CT scan through head of mummy in (b). (d) 3D reconstruction of skull of an ancient Egyptian mummy.

object to generate a cross-sectional image—think of the X-ray beam seeing around corners. There are many different generations of CT scanners; to illustrate the basic principle, we will use the example of a fourth-generation scanner in which an X-ray tube is rotated around an object, as shown in Figure 1. The main difference between the different generations of device is the speed of image acquisition and image quality. In principle, any type can be used for archaeology, the main limitation being the diameter of the aperture.

For any given position of the X-ray tube, a one-dimensional shadow is produced. A mathematical technique called *filtered back projection* is used to convert the multiple shadows into a two-dimensional (2D) image.

The basic concept of back projection is shown in Figure 1. In this case, we have two line shadows of a rectangle. When the corners on the shadows are projected back to the point source of the X-rays they intersect at the position of the corners in 2D space. Although the mathematical technique is in reality far more complex, the end result is the same.

Back projections produce a matrix of numbers, with each number representing the electron density of the material at each location within the object. The back projection method is like a mathematical crossword puzzle. In a conventional crossword puzzle the words in the rows are consistent with the words in the columns. A computer is used to sum the shadows from different directions to produce a 2D array of numbers. These are manipulated to arrive at the unique matrix of numbers, which is the X-ray CT image.

X-ray CT scanners can acquire a sequence of images through an object with a certain slice thickness and slice separation. For example, a sequence of 100 images could be obtained with 4-mm-thick slices spaced 4 mm apart. In this case, the cross-sectional X-ray slices are contiguous—like the slices in a cut loaf of bread. In the same way that a loaf of bread can be thin or thick cut, the thickness of the X-ray slices can be varied. However, unlike a loaf of bread, the X-ray slices can have gaps between them, so, for example, a sequence of 2-mm-thick X-ray slices could be acquired with a 10-mm separation.

Each image pixel has an area and depth and therefore has a volume. This gives rise to the name

voxel, which is short for *volume pixel* (Michael 2001). The value of collecting a sequence of 2D images is that the data can be converted into a 3D image. One method is to cast rays through the block of data to produce a volume rendering of the object. Another method is to extract a surface from voxels of a certain value—like a contour line on a map except in 3D. Examples of a plain X-ray, X-ray CT scan, and 3D reconstruction are shown in Figure 1. The generation of X-ray CT images would not be possible without the use of powerful computers. The development of X-ray CT scanning was paralleled by the development of mini computers, that is, computers small enough to be placed in the same room as a CT scanner.

This discussion has, by necessity, focused upon the generalities of the technique rather than details. Fortunately, there are a number of volumes that describe the underlying physics and mathematics in depth and detail. However, it should be stressed that the majority of books and scientific papers are about medical X-ray CT scanners, since this is by far the greatest use of the technology. Most archaeology scans, especially mummies, are performed using a medical scanner out of hours or an industrial scanner. Some specialist X-ray CT scanning centers exist around the world, for example the μ -VIS X-ray Imaging Centre at the University of Southampton, UK, has a general-purpose industrial X-ray CT scanner also used for archaeology projects and, for example, has been used to scan Roman coins in pots.

One of the main uses of X-ray CT scans in archaeology is the scanning of Egyptian (Hughes, Wright, and Barry 2005) and Peruvian (Applboom and Stuyven 1999) mummies, clay tablets (Applbaum and Applbaum 2005), wood (Stelzner and Million 2015), and soil blocks (Alessandro et al. 2015). An example from an X-ray CT examination of a twenty-second-dynasty Egyptian mummy from the British Museum, London is shown in Figure 1(b–d). The X-ray CT scan was performed at St Thomas' Hospital, London (Hughes 2011) and a sequence of CT scans was used to generate 3D images of the mummy's head and other parts of the body. The CT scans complemented plain X-rays taken in the 1960s and elucidated details of the embalming process. For example, it was ascertained that the brain was removed through the nose rather than

the foramen magnum. A 3D reconstruction of the skull was generated in order to furnish a facial reconstruction.

Computer-Assisted Restoration

ADAM LOWE

Factum Arte, Spain

Digital technology is changing the way we approach heritage preservation. The digitization of paintings, sculptures, architectural forms, early books, manuscripts, and archaeological evidence can provide scholars with new ways of looking at, discussing, and sharing these valuable objects and sites. An important application of digitization is within the field of computer-assisted—“virtual” or “digital”—restoration, a methodology that seeks to question the original appearance of a work of art or site without the need for physical intervention. In digital restoration, diverse forms of high-resolution data can be integrated with conservation records, philological notations, and historical source material using both image-processing and three-dimensional (3D) editing software, thereby addressing the idea of the “original object” by treating originality as a process that changes over time. If conservation is the “management of change,” digital restoration allows us to study that change and understand the reasons an object looks as it does. This is leading to a renegotiation of the relationship between originality and authenticity: There are times when the digitally restored object may be the more authentic, more complete, and more easily understood than a heavily restored and transformed original.

An important aspect of digital restoration is that it allows restorers to rethink physical interventions and follow more cautious approaches when considering their course of action. They can test various propositions before a physical intervention is carried out on the original itself. The high-resolution composite photography and 3D data needed for digital restoration helps to inform decisions and actions. Historians and archaeologists can also employ computer-assisted restoration to visualize theories and investigate

hypotheses about the original appearance and meaning of a work of art. The role of physical facsimiles in the field of digital restoration is changing the way objects are cared for—from their reinstallation in the original location to the reunification of objects separated for different reasons, the emphasis is moving away from the aesthetic display of discrete objects (and fragments of objects) to the awareness that all objects are embedded “things” with a career that reveals not only their original importance but also how they have been valued, appreciated, and understood at different times and in different places. By revealing the changing nature of originality and the decisions that are made during the restoration process, the general public is able to participate in the protection and preservation of the articulate evidence of the past. This approach is bringing art, science, and technology together in the quest for deeper understanding.

A significant role of high-resolution digital archives is in monitoring the condition of an object over time. They are objective records that document the condition of an object at a specific moment in time. This digital information can facilitate a detailed study of the original in case of accident, theft, natural disaster, or iconoclastic attack, or be used to track its condition through the stresses placed on the object by mass tourism. The “digital passport” provides objective evidence in the case of provenance and ownership disputes, insurance claims, and academic discussions.

Methodology of computer-assisted restoration

The methodology behind digital restoration is unique to the specific requirements of each project, although it is possible to loosely define a number of phases. Two case studies from the work of the Factum Foundation for Digital Technology in Conservation are used to illustrate the methodology of computer-assisted restoration.

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

© 2018 John Wiley & Sons, Inc. Published 2018 by John Wiley & Sons, Inc.

DOI: 10.1002/9781119188230.saseas0110

It is first necessary to define the parameters and scope of the digital restoration: What are the objectives? Is the final result virtual or physical? Is it for exhibition display or for the management of vulnerable or remote sites? Is it to reveal the changes an object had undergone? Is it to provide access to the object and reveal its importance? Is it for condition monitoring and to inform restoration decisions? The available materials will in part determine the course of action.

The initial steps involve obtaining color images and a geometrically accurate 3D model, which if possible also captures the subtle surface characteristics that condition our response to a work of art. It is important that the initial color recording is carried out at the highest possible resolution using composite photographic techniques such as panoramic photography, because the work to prepare and merge the image files—elimination of geometric/perspectival distortions and color management operations—reduces the resolution. The result of this step should be an image file that can be significantly enlarged with no loss of quality. All forms of mediation and transformation of the data result in an irretrievable loss and abstraction of information. It is therefore essential to retain both raw and processed files along with a complete history of the actions applied to the digital archive. The “transparency” of the image file will determine the value of a digital restoration, but also enhance the impact it can have as it informs diverse professional decisions.

The recording of 3D information is a relatively new and rapidly developing science. There currently exist a great variety of 3D scanners, each used to document a different aspect of an object or site. Light detection and ranging (LiDAR) scanners can be used to capture geometry quickly and accurately from distances of 1–300 m; white-light scanning technologies record both shape and surface texture from a range of between 0.5 and 1.5 m; and close-range laser scanning technologies can accurately record the surface of objects to submillimeter resolutions. Close- and long-range photogrammetry, a photographic technique to capture color and 3D information simultaneously, is relatively cheap to implement and rapidly replacing more traditional systems in heritage recording. It is currently the case that

the resolution of photogrammetric data cannot match other close-range scanning technologies in either 3D or color resolution. However, recent developments in software and capture methods are enabling conservators and digital restorers to start using photogrammetry as a way to capture surface relief, allowing significantly reduced recording times.

Once data have been recorded and processed, they can be made available to a wide range of specialists in easily accessible forms that are independent of expensive specialist software. These data will inform physical restorations and facilitate research into previous states of conservation by comparing these data with conservation reports, historical images, or accounts of the work of art. Other useful supporting materials may include preliminary sketches, prints, and contemporary copies. If the work is fragmented, damaged, or missing parts, the work of digital restoration will also necessitate academic research. This research will involve the identification of different elements of the same object, obtaining recording permissions, and capturing all fragments at high resolution to ultimately create a virtual or physical archive that reintegrates these elements.

The practice of “digital restoration” can work on many levels. Cracks on the surface of a painting can be analyzed, studied, and removed. Such processes can sometimes be automated using algorithms provided by the software or specially written to reveal the specific physical characteristics that are being studied. Areas of information loss can often be refilled either by cloning surrounding data (when the loss is very small) or by relying on secondary sources when the loss is significant. It is possible to use complex computational, and mathematical methods in the reconstruction of 3D objects, for example, to locate the position of broken fragments. Digital restoration can be performed as an end in itself, a way to better understand the object, or it could inform the physical restoration of a fragmented object.

In all cases, the goal is objective clarity and any changes to the original surface or color need to be “marked” in one way or another. This can be by clearly defining layers within an image file or by using different chromatic codes, to signify

that they are not simply restorations of existing information. Most restoration techniques have an equivalent in the digital domain.

Case 1: The Polittico Griffoni: reuniting and studying a fragmented altarpiece

The *Polittico Griffoni* is an important altarpiece of the Bolognese renaissance painted between 1471 and 1472 by Francesco del Cossa and Ercole de' Roberti for the chapel of San Vincenzo Ferrer in the Basilica of San Petronio, Bologna (Polittico Griffoni). Commissioned by the Griffoni family, the altarpiece remained in San Petronio until the early eighteenth century when the chapel came into the possession of the Aldrovardi family. The *Polittico* was then dismembered and the individual paintings sold. The sixteen surviving panels can be found in nine different museums around the world, including the National Gallery (London), the Louvre (Paris), the National Gallery (Washington), and the Pinacoteca Vaticana (Rome).

The project to reunify the panels of the *Polittico* and restore a facsimile to the chapel of San Vincenzo in the Basilica of San Petronio is a digital restoration aimed at nurturing a deeper understanding of the altarpiece and the artists who painted the panels (Factum Foundation 2018a). The first phase of the work involved composite photography to capture color and a high-resolution 3D laser scanner to record the complex surface of each panel. The recording was carried out over a period of three years in seven different countries. In one case, the data were used to assist restorers during physical restoration—where two panels were recorded before and after the intervention to monitor and document the process. In each case, the custodian will own the data for all current and future commercial applications. In return for this clear statement of ownership, each custodian has agreed to share the data for conservation and study with the other institutions which own parts of the whole ensemble. A digital version of all the paintings recorded will be supplied to each museum (or collection).

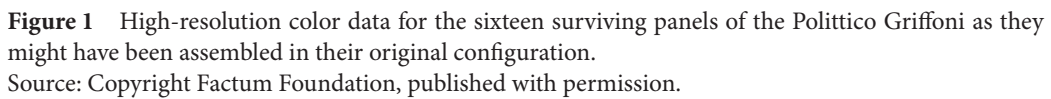

For each panel, it is now possible to view color and 3D information together or separately,

revealing things that cannot easily be identified with the naked eye. While this is leading to a clearer understanding of the reasons behind why each panel looks as it does, the most spectacular part of this “digital” restoration has been the production of a physical facsimile of each painting in its current condition. The individual paintings have been assembled based on new research into how the altarpiece looked when it was first installed in the Griffoni Chapel (Figure 1). The facsimile was installed in the Basilica, thus providing a new context for both the individual panels and the recently restored Griffoni Chapel, itself a historical reinterpretation by Bologna's controversial arts and crafts restorer Alfonso Rubbiani (1848–1913). “On-screen” visualizations may be presented in museums alongside the individual panels, informing discussion about the original design and context of the altarpiece.

Case 2: Wall paintings of the Sala Bologna: digital restoration of lacunae and damaged toponyms

The wall paintings of the Sala Bologna in the Vatican were commissioned by Pope Gregory XIII in 1575 and executed under the supervision of Lorenzo Sabatini. The western wall of the room is almost entirely occupied by a bird's-eye-view map of the province of Bologna. The initial aim of this project was to make a facsimile of this map for the Museo della Citta. However, the facsimile generated interest from the University of Bologna for a virtual reconstruction of the *Map of the province of Bologna*, which would interpret and reintegrate missing areas based on maps and drawings that were discovered in Bologna at the time and other historical research. The digitally restored map gives the viewer a clear and vivid idea of the original appearance of the wall painting. The work was a collaboration between the Factum Foundation and the Alma Mater Studiorum at the University of Bologna, which carried out much of the toponymical research required to “fill in” the missing areas (Factum Foundation 2018b).

The frescoes were initially photographed using a panoramic recording system. This provided the high-resolution color information required

of crack and its location. This was followed by the reintegration of small losses in the landscape. Areas of the *Map* that retained abrasions and rubbings resulting in loss of information were digitally restored by employing both old and new

maps to define the locations of buildings and different features within the various townscapes. It was possible to reconstruct a number of larger lacunae (up to 0.5 m²) thanks to the existence of preliminary painted sketches. The castle of San Martino Manzuoli in Soverzano was reconstructed based on a drawing by Egnazio Danti, which contained sufficient detail to produce an accurate rendition of the missing section of fresco (Figure 2). The drawing was also used to recreate the castle grounds, although specific features were added based on written descriptions of gardens of the period. An interesting reintegration was carried out for a lacuna in the city of Bologna itself: By superimposing a contemporary map of the city over the image of the fresco, it was found that the missing area exactly corresponded with the Basilica di San Petronio. Adapting the design of the Basilica to the style of the map, the building was reconstructed and reintegrated into the representation of Bologna. Several areas that were found to have undergone previous physical restoration were digitally enhanced to “bring back” the appearance of the original. In the end, two versions of the *Map* were produced: one retaining the appearance of the restored areas, the other showing the *Map of Bologna* as it may have looked without historical restorations.

This project is an excellent example of the virtual integration of a number of different historical materials to produce a plausible non-contact reconstruction of the original appearance of a work of art. In the process of the virtual restoration, original research was carried out,

leading to a deeper understanding of the *Map of Bologna* and the biography of its creation.

Conclusion

A new key concept in the digital age is “non-contact,” and although the mantra of the conservation community used to be reversibility, this has recently come under pressure as both practitioners and the general public realize that it can be a relative concept at best and misleading at worst. Digital restoration can ensure that subjective and temporally located decisions are not imposed on original works of art. Moreover, it creates the space for detailed study to be carried out in tandem with restoration and conservation initiatives. Increasingly, digital recording technologies are also facilitating objective records that can be used to monitor change and ensure preservation is both collectively agreed and forensically sound. As exemplified by the case studies discussed above, digital restoration is emerging as a field that can lead to a deeper understanding of heritage and to the objective monitoring of physical interventions. It separates the necessity for subjective projections onto the original object from the desire to understand the original object more deeply. The relationships between originality and authenticity, facsimile, and the need to preserve works of art for future generations are very relevant topics in heritage management, particularly as the world’s population rises above seven billion and more and more people have the means and desire to travel. Pressure is mounting

on heritage sites for a variety of reasons and visitors will need to understand that there is a delicate contract between providing access and the destruction of the articulate evidence of the past.

Digital Cartography

HENRY CHAPMAN

University of Birmingham, UK

Space is fundamentally important to archaeology. From accessing archive information through to recording excavations, there is a heavy reliance on mapping. Over recent decades, there have been a number of parallel developments which have significantly enhanced the ability and rapidity of digital cartography, owing to the development of equipment for capturing data, the increased accessibility to existing digital data including archaeological records and mapping, and the software to process, integrate, represent, and analyze outputs.

While conventions exist regarding the representation of spatial data, the abstraction of space into any cartographic output relies on a number of fundamental considerations, including the spatial scale of the map, its orientation, and its position relative to known features such as roads or buildings. Surveying for the creation of maps can be either achieved in relation to established national, regional, or global coordinate systems which intrinsically reference scale and orientation, or undertaken locally within a “divorced” framework. Increased access to digital mapping resources and the increased sophistication of surveying equipment and data recording have disrupted such divisions. While traditional surveys were always undertaken in relation to the scale at which the mapping would be reproduced, the ability to rapidly collect highly accurate and detailed survey data and the use of digital cartographic techniques such as computer-aided design (CAD) and geographic information systems (GIS) (see Chapman 2006; Wheatley and Gillings 2002) have led to a blurring of issues of scale where survey data can be represented and investigated at varying resolutions. This, coupled with the ability to reproduce and re-task digital data for purposes different to those originally intended, highlights some of the

potential challenges to archaeologists generating digital maps.

Traditional cartographic approaches in archaeology, as elsewhere, relied principally on the measurement of angles and distances. Using equipment such as tapes and chains, coupled with prismatic compasses, optical squares, plane-tables, and theodolites, surveys were commonly undertaken as localized, divorced measurements that could later be manually integrated with existing mapping. These techniques required varying levels of mathematical skill, as reflected, for example, in the origins of the Royal Commission on the Historical Monuments of England within a division of the Ordnance Survey (see Bowden 1999). Typically, survey consisted of two elements: the generation of survey control which provided a network of known positions; and detail survey, using the established control points to pick up details for mapping, such as trench positions or find locations.

The development of digital cartography in archaeology was possible through technical advances in surveying equipment and computer hardware and software. The integration of automatic distance measuring within theodolites led to the creation of total stations (see TOTAL STATION) in the early 1970s which were able to measure angles and distances together through the integration of an electronic distance meter (EDM). This was further enhanced by the development of data-logging equipment that enabled survey positions to be collected automatically, and the increased ability of survey equipment to automatically calculate coordinate positions from angle and distance measurements. The subsequent development of robotic total stations has meant that survey data can be collected by remote control by a single surveyor, and integration with other types of surveying equipment has provided an increased level of freedom in addition to enhanced speed of data collection. Equally, the ability to collect data without the need for a prism has meant that the survey of inaccessible points has become possible.

Perhaps the single biggest impact on digital cartography in recent decades has been the

development of satellite navigation systems (see GPS (GLOBAL POSITIONING SYSTEM)). While commonly referred to as global positioning systems (GPS), there are two principal global constellations of satellites that are used for surveying: the US system called GPS and the Russian Federation system called GLONASS. Other systems in development that currently provide only regional coverage include the Chinese BeiDou system, the European Union's Galileo network, and India's NAVIC system. Collectively, such systems are known as global navigation satellite systems (GNSS) and can be used to establish positions using trilateration of distances from individual satellites calculated using radio transmissions.

In the early years of GNSS surveying there were issues over accuracy, such as the "selective availability" applied to GPS. However, satellite navigation is now providing high levels of accuracy, with the greatest use within archaeology being with survey grade accuracy (typically within approximately 2 cm three-dimensionally). Such accuracy can be achieved either by using two satellite receivers (one static and one recording detail) to correct positions, or through access to regional and national networks of GNSS receivers which can provide equivalent corrections via mobile networks (see Historic England 2015).

The impact of satellite surveying systems on archaeology has been considerable. The ability to directly generate accurate three-dimensional (3D) positions relative to national, regional, or global coordinate systems has significantly increased the ability to undertake control survey (for use by other surveying equipment) and for detail survey. Since GNSS primarily records data in relation to global coordinate systems, larger areas can be surveyed without the problem of elevation accuracy reduction due to Earth curvature. Consistent accuracy means that survey errors are not compounded, which is a hazard with optical methods of survey, and it has become possible to mount satellite surveying equipment on motorized vehicles for the rapid collection of positional information relating to extensive geophysical survey.

The increased rapidity of data collection facilitated by the development of surveying equipment,

in relation to both satellite-based and optical systems, has also increased the ways in which survey data can be used for cartography. In addition to the ability to generate digital mapping rapidly, the ability to collect large volumes of 3D position data has increased the ease by which representations of land surfaces can be interpolated within software packages such as GIS to create 3D representations (or, more strictly, 2.5D), including both general topography and earthworks (e.g., Chapman and Van de Noort 2001). In turn, this has led to the capability to perform spatial analyses of these elevation models to create more abstract representations of space such as of slope, aspect, or even visual relationships.

A fundamental shift in digital cartography has been the development of equipment, software, and approaches for collecting surface data, using techniques such as laser scanning (see LASER SCANNING) and photogrammetry (see DIGITAL PHOTOGRAMMETRY). Whereas other data collection methods normally focus on the subjective collection of specific positions from which digital maps can be created, these methods rely on total capture of data from a prescribed area. The advent of terrestrial laser scanning (see English Heritage 2011), for example, has altered the ways in which digital maps can be created in two principal ways. First, data are collected on the basis of point density rather than specific 3D points chosen by the surveyor. Second, and building from developments with other optical systems, laser scanning can generate 3D data which can represent 3D spaces.

While photogrammetric techniques have been used within archaeology for over a century, digital technology has made multi-image photogrammetry much more accessible and rapid, in addition to providing new tools for representing and analyzing the results. The proliferation of software packages, online tools, and mobile apps means that multiple photographs can be used to generate 3D models of an object or area (e.g., structure from motion (see STRUCTURE FROM MOTION)). This has given rise to the possibility of data-mining photographs of specific sites to generate 3D digital models, as is currently being used in areas of conflict where threats to heritage sites are significant. The current growth in the use of photogrammetry and its ability to be accessible through numerous, less specialist, and

sometimes freely available software is leading to a growth in this area. As with laser scan data, digital photogrammetry generates 3D data from which 2D plans and 3D models can be generated, albeit only after they have been tied into reference information regarding scale, position, and orientation.

The increased ability to generate 3D survey data, particularly from laser scanning and photogrammetry, has been mirrored by developments in software able to deal with the cartographic challenges that such approaches bring. The development of 3D spatial databases such as buildings management systems (BIMs) and other 3D software packages has realized the potential for generating 3D cartographic representations based on survey data. With the increase in the different software packages within which maps can be generated, each with varying levels of interactive capability, there has been some blurring of the boundaries regarding best practice, with the potential for re-tasking data for use in different software packages, including game engines.

Digital cartography is not only dependent on terrestrial survey. The uses of aerial photography (see AERIAL PHOTOGRAPHY), satellite imagery (see SATELLITE HYPERSPECTRAL AND MULTISPECTRAL IMAGING), airborne laser scanning (light detection and ranging (LiDAR); see Crutchley 2010 (see AIRBORNE LASER SCANNING AND LIDAR)), and, increasingly, drones (see DRONES) have provided an ever-growing suite of datasets for generating digital maps and layers of information to add to existing geographical databases. With varying levels of spatial integrity, these methods are generating new ways of capturing spatial data which can be used within cartographic software packages. With multispectral imaging and the ability to capture 3D data from airborne sensors, additional layers of archaeological information can be mapped which might not be visible on the ground or to the naked eye.

The continual development of hardware, software, and applications has meant that digital cartography is set to continue changing. However, despite the increased accessibility to these techniques at relatively low cost, there remain challenges. While survey data will normally be collected for a specific purpose, its “born-digital”

nature coupled with the potential to infinitely reproduce and re-use these data for other purposes raises challenges regarding its suitability, highlighting the importance of maintaining good metadata. This challenge is also seen in the digitization and re-use of data from paper archives where the derived digital version might be represented at scales and resolutions far different to those originally envisaged. A second challenge lies in the archiving of the raw and processed data stemming from digital cartography. The large volumes of data and numerous iterations, matched by the common need for specialist software to process it, mean that sometimes only the derivatives can be easily archived. A third challenge lies in the objectivity of the data themselves. The fundamental difference between surface data collection (e.g., through laser scanning or photogrammetry) and detail survey of 3D positions is that, while the former is effectively an objective record of what the equipment is able to record, the latter relies on specialist interpretation of the most appropriate locations to survey. Aside from the contrasting requirements in terms of expertise, a concern is that insufficient interpretation might be made in the field when collecting surface data, becoming increasingly reliant on what might be interpreted on a computer screen.

Digital technologies continue to make a fundamental impact on the capture and representation of space, through new tools for collecting data and new methods of representing and analyzing the results. While these tools have enabled archaeologists to achieve higher levels of accuracy and consistency, in addition to enabling new and exciting outputs, the shifts that this new technology has brought are also challenging the nature of archaeological survey, mapping, and archiving.

Digital Models of the Land Surface (Digital Elevation and Terrain Models)

RALF HESSE

State Office for Cultural Heritage Management
Baden-Württemberg, Germany

It has long been recognized that topography and geomorphology are key elements in structuring the physical environment (see ENVIRONMENT AND LANDSCAPE) in which human activities take place and to which they relate. These elements include, among other things, settlement, land-use, resource exploitation, and movement. Direct relationships between topography and human activities include, for example, the presence or absence of obstacles to vision or movement, including sea-level change (see SEA-LEVEL CHANGE). Direct relationships can be distinguished from indirect relationships which encompass the topographically influenced presence or accessibility of resources, protection from natural or human threats, and cultural preferences. Examples of indirect relationships are soil differences between upper and lower slopes, exposure of mineral resources, presence of water, exposure to sunlight and precipitation, and presence of particular types of vegetation or fauna. Topography does not, however, determine human behavior. Rather, human response and adaptation to and utilization of particular environments are always subject to technology and culture.

Given the importance of topography and geomorphology as key environmental factors, digital models of the land surface are valuable datasets that can enable and enhance the understanding of past human–environment interactions. Hypotheses relating topographic variables to human activities are developed and tested and can, for example, be applied to “predict” the location of previously unknown archaeological sites (predictive modeling (see PREDICTIVE MODELING)). Furthermore, human activities

leave topographic traces by the intentional or unintentional removal, movement, or deposition of material. Such traces can be detected in high-resolution digital terrain models (DTM) and are frequently used in archaeological prospection.

Digital models of the land surface can broadly be divided into models of the actual ground surface excluding vegetation, buildings, and so on (DTM) and models including vegetation, buildings, and so on (digital surface models (DSM)). While some inconsistencies in the use of these terms prevail, the term digital elevation model (DEM) is often used either as an overarching term for both DTM and DSM or synonymously with DTM. These digital models are used in a variety of different data structures and file formats. The most common data structures are point clouds, triangulated irregular networks (TIN), and rasterized elevation maps. A point cloud contains X, Y, and Z coordinates of a large number of individual, usually irregularly spaced, points. A TIN contains X, Y, and Z coordinates of a large number of individual, usually irregularly spaced, points which are linked in a network of nonoverlapping triangles. A TIN is, after optional selective thinning, created from a point cloud by Delaunay triangulation that connects all points into triangles and ensures that none of the points is inside the circumcircle of any of these triangles. A rasterized elevation map contains a regular grid of elevation values. A rasterized elevation map can be created directly from a point cloud using binning and interpolation or from a TIN created as an intermediate product. The terms DEM, DSM, and DTM commonly refer to a rasterized elevation map but can also refer to a TIN.

Most analytical and visualization applications require continuous surfaces rather than individual points. While the nodes in a TIN commonly represent actual point measurements, the elevations in areas where no measurements exist are derived by interpolation based on neighboring points. In a TIN derived from digitized contour lines or from a gridded elevation map, all values are usually derived by interpolation. Different interpolation algorithms

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

DOI: 10.1002/9781119188230.saseas0627

(e.g., bilinear interpolation, inverse distance weighting, kriging) exist and will produce different results. Results may differ by algorithm type and some may represent the true surface better than others or may be visually more pleasing (Mitas and Mitasova 1999). However, as interpolation does not add information, neither a TIN nor a rasterized elevation map can resolve detail smaller than the distances between actual point measurements. The application of digital elevation data at resolutions higher than that of the underlying elevation measurements is therefore problematic. The advantage of a TIN derived from actual point measurements over a rasterized elevation map is that the former preserves the measured elevation data and that it allows spatially variable point densities which can improve the representation of break lines. A rasterized elevation map has the advantage of smaller file size. This is because only elevation values have to be stored in a rasterized elevation map rather than X, Y, and Z coordinates plus edges in a TIN. A rasterized elevation map also allows the easier computation of parameters such as slope, aspect, and convexity or relief visualization.

There are various methods for the acquisition of digital elevation data. Traditionally, DTMs have been created from digitized map contours. Today, this technique is mainly used for the reconstruction of historical topography. Because ground-based topographic survey using the global positioning system (GPS) (see GPS (GLOBAL POSITIONING SYSTEM)), DGPS, or Total Station (see TOTAL STATION) is slow, most methods now rely on remote sensing (see AIRBORNE REMOTE SENSING) approaches such as airborne LiDAR, terrestrial LiDAR (see TERRESTRIAL LIDAR), synthetic aperture radar (see SYNTHETIC APERTURE RADAR) (SAR), or digital photogrammetry (see DIGITAL PHOTOGRAMMETRY). Digital photogrammetry uses image-based 3D modeling (see IMAGE-BASED 3D MODELING), multi-view stereo (see MULTI-VIEW STEREO), or structure from motion (see STRUCTURE FROM MOTION) with aerial photography (see AERIAL PHOTOGRAPHY) from various platforms including drones (see DRONES). Achievable spatial coverage and resolution, as well as penetration of vegetation, depend largely on the method of acquisition. For most applications in archaeology, airborne LiDAR has become the method of

choice due to its unmatched ability to penetrate forest canopy, its high spatial resolution, and potentially very large area coverage (Doneus and Briese 2011). Irrespective of the method of 3D point data acquisition, the raw point cloud usually contains a considerable quantity of non-ground points (commonly vegetation and/or buildings). Creating a digital model of the actual ground surface (a DTM) requires the removal of any such points. Technological progress in recent years encompasses increasing spatial resolution, improvements in vegetation filtering due to the application of advanced filter algorithms and full waveform scanners, and the possibility to penetrate shallow water with bathymetric LiDAR (Doneus et al. 2013). SAR, specifically the near-global shuttle radar topography mission (SRTM) DSM, is frequently used when the topography of very large areas is analyzed. Image-based 3D modeling is used in particular for the generation of local DSMs (and DTMs in nonvegetated areas) and is praised as a rapid and low-cost approach.

A major motivation for using digital models of the land surface in archaeology is the enormous analytical and modeling potential of such data (Opitz and Cowley 2013), in addition to the often compelling visual impression and the landscape-scale presentation of archaeological sites and their environments. Computations of slope, aspect, relief curvature, automated landform classification, and the modeling of environmental parameters with the aid of topographical data (such as wetness indices, runoff and erosion potential, and soil properties) provide baseline data for assessing archaeological sites and their environments. (Inter)visibility modeling (see VISIBILITY MODELING)/isovist analysis (see ISOVIST ANALYSIS) can be performed for different scenarios using a DTM, actual DSM, or modeled DSM with known or hypothetical past vegetation cover (Wheatley and Gillings 2000). Modeling of solar illumination and derived parameters under such scenarios can provide insights into microclimatic conditions at site and landscape scale and can in turn be used in vegetation modeling. Computations of topographical prominence can be based on known or hypothetical perceptions and functions of landscape elements and can be used to assess hypotheses regarding site placement and

function. Cost-surface analysis and least-cost paths (White and Surface-Evans 2012) provide tools for testing hypotheses about known routes, as well as for finding unknown or likely routes. For modeling results to be relevant to the archaeological questions posed, all relevant assumptions must be stated clearly and, if possible, be justified by evidence. Finally, digital models of the land surface are key elements in virtual reality modeling (see VIRTUAL REALITY MODELING) applications at landscape scales.

Perhaps the most common current application of high-resolution digital terrain models is archaeological prospection. This has rapidly gained importance with the increasing availability of high-resolution DTMs derived from airborne LiDAR (Doneus and Briese 2011). As many human activities such as agriculture, mining, movement/transport, settlement, and ritual have left traces in the topography, these traces can be used to detect and map archaeological features and sites. Such mapping efforts have contributed to the recognition of archaeological landscapes and the trend of considering archaeological evidence and interpretation at a landscape scale. Because many traces of past activities are relatively minute in comparison with the landscape forms on which they are superimposed, advanced LiDAR data visualization and processing techniques (e.g., Štular et al. 2012; Kokalj and Hesse 2017) are increasingly used to generate data products that facilitate archaeological interpretation (see LIDAR DATA VISUALIZATION AND PROCESSING). Together with the penetration of forest canopy and the availability of LiDAR data for very large areas, the resulting ease of desk-based mapping and prospection has led to a revolution in how landscapes are treated in archaeological research (Chase et al. 2012).

With increasing spatial coverage, availability, and resolution of DEM and the ongoing development of analytical tools, including geographic information system (GIS) and relief visualization techniques, an increasingly widespread use of such data can be observed. Visual presentation and spatial analysis of archaeological sites and landscapes, as well as large-area archaeological prospection in forested areas, now commonly rely heavily on the application of digital models of the land surface. While the technological advances and the increasing focus on quantitative

approaches have indeed been revolutionizing archaeological practice, their implications for archaeological theory may require more attention (cf. Verhagen 2012).

Digital Photogrammetry

ADAM BARNES

University of Arkansas, USA

Digital photogrammetry is an image-based, three-dimensional (3D) measuring technique that typically involves a series of digital images where subsequent camera locations and orientations produce overlapping views of an object (e.g., a ceramic pot or stone structure) or a surface (e.g., a landscape from an aerial perspective). The overlapping portions of each image pair (known as a stereopair) provide the stereoscopic parallax required for most photogrammetric processes, including the measurement of discernable points in 3D space. To be precise, digital photogrammetry includes measurement techniques involving a single image, but the term is predominantly used to refer to stereophotogrammetric methods, which will be the primary topic of this definition.

Digital photogrammetry is a flexible and relatively straightforward process, making it useful in a wide variety of scientific and commercial applications. These applications range in scale from astronomical (e.g., measuring the position of celestial objects) to near-global (e.g., using large collections of satellite images to model the Earth's surface) to microscopic (e.g., using photomicrography to measure small objects not visible to the naked eye). These applications can also range in monetary cost from extremely expensive to nearly free (assuming users already own a digital camera and computer).

Digital photogrammetry can potentially involve a number of different input data types, including images from both active (e.g., radar or sonar) and passive (e.g., photographic) sensors. The most common sources of imagery are sensors found on imaging satellites, aerial camera systems, digital single-lens reflex (DSLR) or other consumer-grade cameras, and digitized film-based photographs (e.g., scanned historic aerial photography). Image sets for a given project can be captured by a single device from multiple

locations, or by multiple devices stationed at various locations. If a single imaging device is used, the subject and surrounding scene are typically static. When multiple, synchronized imaging devices are used, a single instance of a moving object or scene can be captured.

At the most basic level, photogrammetry is accomplished by calculating the 3D intersection of two or more vectors that are defined by the relationship of (1) a measured point on an image, (2) the location and orientation of the camera at the time of image capture, (3) the intrinsic properties of the camera and lens used to capture the image, and (4) the position in 3D space of the point measured on the image. This relationship is described by collinearity equations and, during the photogrammetric process, is iteratively refined by a process known as bundle adjustment (Brown 1976).

The two basic categories of photogrammetry are aerial photogrammetry and close-range photogrammetry (CRP). Industry and research applications of both aerial and CRP vary widely. From the doctor's office to the manufacturing floor, photogrammetry is used to quickly reconstruct accurate 3D models of real-world objects and to guide automated processes. These models and processes include a range of scenarios, such as mapping and survey, spatial analysis (see SPATIAL ANALYSIS), site/object documentation and dissemination, 3D feature extraction, rapid prototyping, tool/part inspection, deformation monitoring, clash detection, automated part assembly, motion tracking, robot navigation, and many others.

Aerial photogrammetry is defined by the use of digital images with an aerial perspective captured by a camera or other digital sensing device while mounted to an aerial vehicle or imaging satellite (see AERIAL PHOTOGRAPHY). These images are commonly used to create mapping products, such as digital surface models (e.g., a digital elevation model of the Earth's surface) and orthorectified images (geolocated, near distortion-free images with map-like properties). Traditionally, aerial photogrammetry involved

DOI: 10.1002/9781119188230.saseas0191

carefully planned flights using aircraft rigged with specially designed and calibrated film-based metric cameras. Today, a wide variety of aerial- and orbital-based digital sensing devices exist. Global navigation satellite systems (GNSS) and modern photogrammetric software provide, in some cases, automated tools for calibration of geometric and radiometric sensor properties, and the output of map-ready digital files useful to a wide variety of users.

CRP involves images captured from some lesser distance than aerial photogrammetry, including images captured from low-altitude aerial (e.g., low-flying unmanned aircraft systems (UAS)) and/or terrestrial based platforms (e.g., a standard tripod). Image sets for CRP can be captured in a relatively short amount of time and do not require a professional-level DSLR. Regardless of what camera is used, the photographer will ideally have the skills necessary for taking sharp, well-exposed photographs that frame the object tightly, making efficient use of the available sensor area. Common uses for CRP include the 3D documentation of structures or objects, crime scene investigation, and metric analysis of complex objects or surfaces.

For any digital photogrammetric project, the potential density of measurements and precision with which any individual measurement can be made will, in part, be connected to (1) the distance from the camera to the object, (2) the sensor size/resolution of the camera, and (3) the focal length of the lens. Together, these three variables determine the size that any given pixel in an image occupies on the surface of the subject being imaged. This value, equal to the distance between the center of two adjacent pixels as measured on the subject's surface, is known as ground sample distance (GSD). Projects are commonly planned with GSD in mind, as it can be a limiting factor for the usefulness of certain project outputs.

Aerial and CRP projects involving a surface (e.g., a landscape or vertical wall-like surface) will typically result in one or more linear strips of parallel stereo images. In this case, the optical axis of each camera location is parallel to one another and do not intersect. To ensure complete coverage, camera locations are usually arranged in blocks where the viewable area of subsequent images within a single strip will contain 60–90 percent forward overlap, and subsequent strips

will contain 50–70 percent side overlap. Projects involving an object imaged from multiple angles will result in an image dataset of convergent stereo images, meaning the optical axes of subsequent camera locations will intersect at some point in space.

Inherently, the scale, position, and orientation of any photogrammetric model is arbitrary, although most software will initialize the coordinate system using the location and orientation of the first camera station. Therefore, projects requiring the photogrammetric model to be accurately scaled or situated within an existing reference frame will need to integrate sufficient reference points with known dimensions and/or coordinates. These reference points are commonly referred to as ground control points, or simply control points. As a minimum, reference information required for scaling a photogrammetric model would include a scale bar or other object of known length visible in two or more photographs, or two control points (also visible in two or more photographs) with known 3D coordinates. Beyond scaling, the orientation of a photogrammetric model requires, as a minimum, two control points with known 3D coordinates and one control point for which only one coordinate (x , y , or z) is known.

The accuracy of the reference information used to scale the photogrammetric model will determine the scale-accuracy of any data output. If the minimum control is provided for model orientation, then the accuracy of that reference information will only affect the position and orientation of the model within the reference frame, and will not contribute to the relative accuracy of the output model except for scale. If more than the minimum control is provided for model orientation (i.e., three or more control points with known 3D coordinates), it is important to understand that the accuracy of these control points can (depending on the settings within the photogrammetric software being used) influence all aspects of the photogrammetric solution (e.g., refinement of camera calibration, determination of image locations/orientations, and ultimately 3D model shape), in addition to the position and orientation of the model within the reference frame.

The history of photogrammetry is long. Well before digital photogrammetry (in fact, well before the invention of photography), scientists

were developing the mathematic principles required for such work. For example, publications on linear perspective in the early eighteenth century were proposing its usefulness in cartography. By the end of World War II, aerial photogrammetry was widely used for the production of topographic maps, one of the earliest and most dominant applications of photogrammetry (Wolf and Dewitt 2000). Around this time photogrammetry was done in an analog fashion with mechanical instruments; hence this phase of photogrammetry is now referred to as analog photogrammetry. The next phase, starting in the late 1950s, introduced computers to the photogrammetric process, which provided the computational power necessary for applying previously known mathematical principles. This phase is now referred to as analytical photogrammetry.

The beginnings of digital photogrammetry (circa 1990s) involved a move to fully digital setups, including computer-based photogrammetric software and digital images. This removed some of the complicated steps involved with earlier phases, but still included rigid conditions for camera calibration, image capture (camera settings and location selection), and overall processing, which remained a tedious and primarily manual operation. While this may still be true for projects requiring the highest degree of accuracy, digital photogrammetry today can be used to produce high-quality 2D mapping products and/or 3D models using inexpensive, off-the-shelf, nonmetric cameras and free, open-source computer software or web-based (cloud computing) services that are highly automated and easy to use.

Increases in computer processing speeds and memory over the past decades, along with advances made in computer vision research, have triggered an acceleration in the use of digital photogrammetry. Feature detection algorithms from the field of computer vision (namely SIFT, or scale-invariant feature transform, but also other similar object recognition methods) have led to the development of important image-based 3D reconstruction algorithms. The introduction of structure from motion (see *STRUCTURE FROM MOTION*) and multi-view stereo (see *MULTI-VIEW STEREO*) techniques to the photogrammetric process have essentially removed some of the

cumbersome requirements and time-consuming procedures associated with photogrammetric data capture and processing. Perhaps more importantly than making the photogrammetric process easier, these techniques have also increased the density of measurements that can be made with photogrammetry within a short period of time.

It is now possible to produce a single 3D measurement from nearly every pixel of every image within a photogrammetric project, easily obtaining millions or even billions of individual measurements. The product of this dense collection of measurements is commonly referred to as a 3D point cloud. Dense 3D point clouds can then be used to create a mesh of connected polygons, essentially defining the surface of the originally surveyed object. Current trends include the use of 3D polygonal mesh models in downstream software packages and digital environments such as computer-aided design, geographical information systems, 3D animation and gaming, augmented reality (see *AUGMENTED REALITY*), and others. These models can also be shared among researchers and/or the public for the purposes of research and education in the form of 3D printing (see *THREE-DIMENSIONAL (3D) PRINTING AND ADDITIVE MANUFACTURING*), interactive virtual worlds or games (see *VIRTUAL REALITY MODELING*), web-accessible virtual museums, and archival databases.

It is quickly becoming clear that the use of UAS will have a profound effect on a number of industries involving photography, videography, survey, search and rescue, and many others. This will likely lead to an increased awareness of the many uses for photogrammetry and other remote sensing technologies. CRP projects have always benefited from inclusion of images captured from an elevated perspective, and UAS clearly provide this at a lower cost than traditional aerial platforms. UAS can be piloted by a human operator or execute a predetermined flight path in a fully automated fashion, returning to some home base once the flight is complete. This technology, which can be used to provide repeatable high-resolution image datasets for photogrammetric processing, is already being used for a number of industries involving an often changing landscape, such as precision agriculture, and have

enormous potential for the monitoring of fragile and/or threatened archaeological landscapes.

Geometric Matching

IVAN SIPIRAN

Pontificia Universidad Catolica del Peru, Peru

PAVLOS MAVRIDIS and TOBIAS SCHRECK

Graz University of Technology, Austria

Objects of interest in archaeology and many more domains are often characterized by geometric properties, which in turn may determine important aspects like shape and function. Geometric matching is the problem of finding correspondences between geometric representations, which in turn are obtained from appropriate notions of similarity of object geometry. Practically, object geometry is most often described in two-dimensional (2D) or three-dimensional (3D) Euclidean space. Computational methods for geometric matching provide a basis for many useful applications in archaeology (see *COMPUTER APPLICATIONS IN ARCHAEOLOGY*). For example, in virtual restoration (see *COMPUTER-ASSISTED RESTORATION*), the automatic reassembly of 3D models from digitized object fragments can be realized by searching for geometric matches between fracture surfaces. Also, object self-similarity can be computed by geometric matching, allowing researchers to paint-in missing parts of an incomplete object using input from the object itself. For 3D digitization, often many 3D views from a given object need to be merged, and matching of overlapping parts of these views can help to automatize this process. Also, matching can be applied to automatically identify correspondences between object parts (see *CORRESPONDENCE ANALYSIS*), supporting object analysis and interpretation. As a further example, geometric matching can be used to implement geometric search engines, allowing users to retrieve geometrically similar objects from object databases. While the focus of this survey is on methods for geometric matching in the 3D case, many methods can be adapted to also work for 2D situations.

Matching models

Geometric matching methods can be roughly divided into two general categories. Feature-less algorithms determine the matching between geometric surfaces by taking into account every point that belongs to these objects. In contrast, feature-based algorithms accelerate the matching procedure by first determining a set of salient feature points (or simply features) on the surfaces of interest and then trying to determine correspondences between these feature points. This way, the size of the problem is reduced and the computational efficiency is improved. However, determining reliable features can be very challenging when large amounts of noise exist in the input data, something that happens when scanning reflective objects using optical data acquisition methods or when using low-cost and low-precision 3D scanning devices. For these reasons, both feature-less and feature-based matching algorithms are used in practice, depending on the characteristics of each dataset.

Feature-less and feature-based geometric matching methods mostly take into account the geometry of the surface. However, their precision can be improved by using additional information when available, such as material or texture properties.

Feature-less matching

Finding the optimal geometric matching between multiple surfaces is a challenging optimization problem, where a search algorithm must search between many, if not all, possible solutions in order to find the optimal one. Local matching algorithms search around an initial starting solution for a locally optimal one, while global algorithms search, or stochastically sample, the entire space of possible solutions to find the globally optimal one. Global algorithms often trade matching accuracy for a more efficient inspection of the entire search space, but after they approach

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

© 2018 John Wiley & Sons, Inc. Published 2018 by John Wiley & Sons, Inc.

DOI: 10.1002/9781119188230.saseas0256

the optimal solution, they can be combined with a local algorithm for improved accuracy.

Local geometric matching is usually performed with the iterative closest point (ICP) algorithm, or one of its variants. This algorithm iteratively alternates between a correspondence determination step and a rigid-motion computation step. In the first step, closest-point correspondences are determined between the two shapes, where each point of the first shape is assumed to be corresponding to the closest point from the second one. Given these correspondences, the second step analytically computes the optimal rigid motion that aligns the shapes. After rigidly moving the shapes according to this computation, the same process is repeated iteratively. After a few iterations, the algorithm converges to a locally optimal solution that aligns the two shapes, a process that is also called registration. If a matching score is required, it can be computed by measuring the quality of the alignment (such as the average distance between the two surfaces). Many ICP variants improve the convergence speed and/or the robustness to noise and outliers.

As a local registration algorithm, ICP can determine the globally optimal alignment only if the initial pose of the shapes is close to the optimal one. When this is not the case, ICP should be combined with a global registration algorithm. Such algorithms are often based on well-known global search methods, such as simulated annealing, random sample consensus (RANSAC), or geometric hashing.

In simulated annealing, the matching problem is modeled as a function of six continuous variables: three for the position and three for the rotation. Given that these variables define a specific alignment, an objective function can evaluate the matching score as the distance between the two objects. The algorithm stochastically searches the entire space of possible solutions, starting from a (possibly random) initial position and jumping to neighboring solutions, by changing (or jittering) one or more variables. The direction and the length of the jumps depends on the values of the objective function at the current and previously visited points of the search space. Given enough iterations, the algorithm will approach the optimal solution, which can then be accurately determined with ICP.

Similar to simulated annealing, RANSAC is also a stochastic search algorithm, where the algorithm iteratively generates a random solution (hypothesis) to the problem and then tests it for correctness. The algorithm terminates when the probability of finding a better hypothesis is lower than a threshold. In geometric matching problems, the hypothesis can be generated by selecting a set of random points from the first surface, and then trying to determine an equally numbered set of corresponding congruent points in the second surface. The transform that aligns these two sets of points forms the hypothesis, which is then tested by measuring the geometric distance of the transformed surfaces.

Geometric hashing provides an alternative method to search the six-dimensional space of possible alignment transformations. First, the search space is quantized into nonoverlapping cells, and then for random pairs of congruent point-sets from the first and second shape, the transform that aligns these sets casts a vote to the corresponding cell. After taking multiple random pairs, a matching score can be determined by applying the transformation with the highest number of votes and counting the amount of overlap in the transformed shapes.

Geometric matching algorithms, such as *k*-sparse (Mavridis et al. 2015), can also be used to detect symmetries in an object, by registering an object with itself and enforcing partial-overlap or by reporting all possible solutions to the user.

Feature-based matching

In feature-based methods, the matching is based on certain shape features computed during a feature detection and description stage. Depending on the implementation, they can be computationally efficient as they may take into account a smaller amount of information as compared to all points of the input geometries. Also, depending on the feature definition, feature-based methods may implement shape abstractions, allowing them to match geometry under invariances (e.g., regarding noise, scale, level of detail, or nonrigid deformations).

One may distinguish global and local feature-based methods. Global features are computed

taking all input geometry into account. The main classes of global features proposed to date include view-based features (e.g., computed from renderings of the geometry), structural features (e.g., computed from line skeletons of the geometry like medial axis), surface features (e.g., computed from surface curvature), or volumetric features (e.g., volume histograms). Geometric features can be encoded in appropriate data structures including vectors, graphs, or histograms, yielding so-called geometric descriptors. The matching problem can then be solved by computing an appropriate distance function between pairs of geometry descriptors, and declaring a match based on thresholding the feature-based distance scores. Feature-based methods are often used in combination with statistical data analysis (e.g., for dimensionality reduction or feature selection to obtain compact descriptors); for comparative surveys of global geometry features see Tangelder and Velthkamp (2008) and Bustos et al. (2005). Recently, deep neural network technologies in combination with views of the considered geometry have shown to be effective for classification and feature extraction (Bai et al. 2016).

In contrast, local features are computed in particular regions of the geometry, with predominance of distinctive regions. Again, local features can be also encoded in vectors which can be subsequently analyzed using an appropriate distance. The local characterization of the geometry allows us to include robustness to transformations or missing geometry, which is a common problem in archaeology. For example, broken objects could be considered as partial shapes that can be reconstructed by using templates derived from similar models found in a shape repository (Savelonas, Pratikakis, and Sfikas 2014). Moreover, the study of local patterns in the heat distribution of surfaces has proven to be an effective way to find symmetrical structures in heritage objects (Sipiran, Gregor, and Schreck 2014). Symmetric correspondences can be found using a matching algorithm that counts validation votes based on geometric predicates. Subsequently, the symmetric correspondences with a high number of votes generate a symmetric transformation which, once applied to the original model, is able to generate missing portions of the object. This approach can be used to complete damaged archaeological objects.

Summary

Feature-less and feature-based methods allow us to implement geometric matching, which is needed in many applications dealing with 3D object data. The choice of method will typically depend on the practical requirements at hand, including the need for matching precision (possibly under invariance and robustness requirements), as well as computational efficiency. We note that feature-less and feature-based methods need not be used exclusively, but may be applied in combination. For example, efficient matching for large shape datasets can be implemented by first running a fast feature-based filtering stage, followed by a computationally more complex, but more accurate feature-less matching stage for refinement of the results.

Geometric Modeling

ARLEYN W. SIMON and DIANNE HANSFORD

Arizona State University, USA

ANSHUMAN RAZDAN

University of Delaware, USA

Archaeological research is largely based on the systematic excavation and analysis of material culture to interpret the three-dimensional (3D) world of past societies. Geometric modeling approaches may be applied to objects, features, and structures that were integral to the *milieu* of lifeways at the intersection of cultural and natural realms.

Overview

Geometric modeling, also known as computer-aided geometric design (CAGD), has become increasingly important to archaeological documentation, analysis, and interpretation. Geometric modeling is the study of computational and geometric aspects of curves, surfaces, and volumes. It is an inherently interdisciplinary area, drawing from a body of knowledge including mathematics, engineering, and computer science.

Traditional application areas included computer-aided design (CAD) systems used by engineers and designers, games and movies, scientific visualization, and medical image processing. With advances in data capture, increased computing speed, and less-expensive storage, more disciplines have access to 3D data and thus a desire to describe shapes and analyze these representations. Hence, geometric modeling has become an important tool for scientific domains such as archaeology. The geometric modeling toolkit can be separated into three phases: data capture, creation of geometric models, and geometric analysis.

Data capture

Data capture, also referred to as digitization or scanning, pertains to capturing inherent details of a physically existing form into a digital representation. Data capture can be regarded as a discipline in its own right (Farin, Hoschek, and Kim 2002) and various data capture methods are employed including photography, generating pixel data (see COMPUTATIONAL PHOTOGRAPHY); laser scanning, generating 3D point clouds (see LASER SCANNING); remote sensing (see AIRBORNE REMOTE SENSING) and computed tomography (CT) scans, generating volume data (see COMPUTED TOMOGRAPHY).

Geometric processing methods are essential to preparing data for representation and analysis. A triangulation must be computed for a 3D point cloud, imparting a topology to the data and also converting the point cloud to a surface representation. Geometric decimation methods and mesh optimization are essential for creating optimal-sized datasets, removing redundant data, or improving visualization. Detecting noise and removing it from the data is also important (Farin et al. 2002).

Features refer to attributes (shape, color, texture, functionality, etc.) that are important to the particular domain community. Segmentation is defined as breaking down an object into a set of simpler objects based on features. Segmentation can be hierarchical. For example, a vessel could be defined as a combination of base, body, neck, and spout. The body itself may comprise several functional elements. Feature identification and segmentation is important for making the data more manageable and improving the representation (Schurmans et al. 2001; Razdan et al. 2004).

Model creation

Representation of geometric surface models can be carried out with triangle meshes or as a set of explicit, implicit, or parametric equations (Farin et al. 2002). For continuous surface models, the latter is the favored method because of flexibility

in design and ease of analysis. The final representation may depend on many factors, such as storage space, precision and accuracy to recover original data, and ease of downstream data usage. Bézier and B-spline parametric curve and surface representations are the most prevalent because they offer geometrically intuitive control polygon-based design handles (Farin 2002). These surfaces are sometimes called free form surfaces or sculpted surfaces. They are made of polynomial functions in each coordinate. If an exact representation of conics (e.g., ellipses) or quadric surfaces (e.g., spheres) is to be modeled, then nonuniform rational B-splines (NURBS), which are based on rational polynomials, should be used (Farin 2002). A parametric curve or surface can be readily analyzed or put into a simulation model. Additionally, modification of a parametric curve or surface is far easier than editing a triangle mesh.

Geometric models may be constructed as the solution to a data-fitting problem or in a design scenario. Least-squares fitting of a B-spline surface is the most common method for finding an approximation to 3D point cloud data (Farin et al. 2002). Complex datasets necessitate segmentation of the data into similarly shaped, continuous regions; this can aid in determining necessary parameter values for each data point. Smoothing equations for improved shape, called fairing, are easily employed, but at the expense of quality of fit.

For some applications, a triangle mesh representation might be sufficient, particularly since laser scanners can produce very dense point clouds. Geometric analysis methods, many of which are based on ideas from continuous geometry, can be approximated on a triangle mesh. Somewhat related to triangle meshes are the methods of subdivision surfaces, which take a polygonal mesh as input, carry out refinement steps, and result in smooth-looking surface models. Model design time can be quite fast and these methods are popular in areas where visual appearance is important but tolerance and analysis are not.

A large part of geometric modeling is concerned with the construction of continuous geometric models. A wide range of construction techniques are available for surface models. For example, the Coons method is based on

building a surface between four given boundary curves (Farin 2002). For example, a region of a ceramic pot that was missing can subsequently be filled in. CAD systems offer a wide range of construction techniques geared toward particular design scenarios and nearly all CAD systems are based on rectangular patches built as B-spline or NURBS surfaces. Volume modeling methods deal with visualizing scalar, vectors, or tensors in 3D space. A popular surface extraction technique, called marching cubes, generates contour surfaces as triangular meshes (Farin and Hansford 2000).

Geometric analysis

Many curve and surface interrogation methods are available. Curvature plots and comb plots for curves and curves on surfaces are available in nearly every CAD system. For surfaces, Gaussian curvature is widely used to analyze local surface geometry by classifying surface shape as one of three fundamental surface types: elliptic, hyperbolic, or parabolic. Gaussian curvature may be color coded and texture mapped onto the pot. Other surface curvature measures include mean, absolute, and root-mean-squares curvature. These measures reveal shape characteristics and irregularities of the surface, including profile or planar section analysis. Curvature of a planar section is analyzed to check for symmetry of the object. Additional examples of surface interrogation techniques include contouring, reflection lines, and geodesics (Farin 2002).

Archaeological applications

As technological advances in data capture hardware and software have been realized, applications to archaeological research have expanded rapidly to include microscopic phenomena, objects and artifacts, structures and architecture, and settlement systems and natural landscapes.

Archaeological analyses of natural and cultural objects and artifacts utilize geometric modeling to visualize internal features (volume modeling) and external features (surface modeling) (Schurmans et al. 2001). Internal cellular structures are modeled as they form and change

over time and modeling of articular joint surfaces facilitates studies of biomechanics. Modeling conjoinable surfaces can assess lithic reduction sequences. Variation and symmetry in ceramic vessel morphology provides measures of standardization. In reductive and additive technologies, geometrically meaningful features are identified as geometric pattern primitives, and their segmentation refines evidence of technological traditions.

Subterranean 3D surveying, scanning, and geometric modeling are contributing to accurate georeferenced mapping of natural and cultural features in cave sites (González-Aguilera et al. 2009). Terrestrial laser scanning produces integrated multiscaled models of geological formation processes and Paleolithic art applied to dimensional surfaces. Time-of-flight pulse and triangulation scanners used with artificial targets register datasets to a common reference system. Digital photography provides detailed color and textural maps. Processing proceeds from point cloud, to 3D mesh, to feature extraction and matching, to co-registration and computational parameters. Geometric CAD models have been used to construct cave replicas (e.g., Altamira) that are open to visitors while reducing impacts on the delicate sites.

Architectural studies of domestic, public, and religious structures present unique construction materials and techniques, preservation, and internal and external configurations. Traditional plan and profile drawings and photography are 2D, but are limited in perspective, accuracy, and interpretation. Architectural knowledge is developed with interdisciplinary discussion and analysis of junctures between cultural and natural forms (Colonnese, Carpicci, and Inglese 2016). Architectural complexities are illustrated with georeferenced altitudinal topographic models that detail the relationships among structures, landforms, and connecting passageways. Geometric models provide accurate 3D relational contexts to examine hypotheses regarding access, construction, and cultural relationships.

Geometric modeling and analyses are also applied to irregular earthen and shell mounds (Magnani and Schroder 2015). Model building from stereo photogrammetry (see DIGITAL PHOTOGRAMMETRY) generates mound size and

volume, details erosional processes and modifications, and provides 3D templates for restoration efforts. Techniques including structure from motion (see STRUCTURE FROM MOTION) (SFM) can provide accurate yet efficient methods of architectural documentation and guides for restorations.

Exploration of settlement patterns and landscape use in tropical settings has been thwarted by inaccessibility and vegetation overgrowth of architectural ruins and agricultural modifications. Recent advances in aerial light detection and ranging (LiDAR), where point cloud data have been filtered to remove noise from vegetation, have produced accurate and detailed modeling of ancient Mesoamerican structures, settlements, and agricultural terracing (Carter et al. 2012). International terrestrial reference frames with X, Y, and Z and global positioning system (GPS) coordinates also produce accurate geometric model maps of feature dimensions and elevations.

Future directions

Geometric modeling has opened a new era of exploration that benefits archaeology, geomorphology, and geology. We have outlined a pipeline of geometric modeling tools and given examples of their use in archaeological research. Advances in these tools can be made with more collaborative, interdisciplinary projects between domain scientists and the geometric modeling community, building custom tools for specific applications. These collaborations are most successful when the domain scientists become familiar with the vocabulary of geometric modeling. Additionally, an understanding of what underlies software applications for geometric modeling and visualization can help avoid producing erroneous results. The references provided are good starting points to explore key concepts and additional resources.

Future collaborations can contribute to building better geometric models more efficiently. Also, more advanced analytical capabilities to work with geometric models would provide researchers with better tools to extract measurements and define quantifications and dimensional

aspects of interest for comparative research. In turn, these capabilities will improve indexing and querying multiple models in large-capacity databases. Advancing geometric documentation and knowledge of heritage materials will support preservation efforts in recording sites, features, and artifacts for posterity, especially with continuing risks of damage or destruction through acts of conflict, vandalism, and natural disasters.

Human–Computer Interaction Research

PATRICIA MARTIN-RODILLA

Institute of Heritage Sciences, Spanish National Research Council, Spain

The study of the connections and interdependencies between humans and machines has been a constant focus of interest for research communities since historical times. Historical processes such as industrialization, arms development during World War II (e.g., the foundation of the Ergonomics Research Society in 1949 (Dix et al. 2003)), and the emergence of personal computers and personal applications (such as text editors and spreadsheets, or personal consoles for videogames) resulted in the formation of a new research area by the late 1970s. This new research area specialized in studying the relations between computer technology and human users. In particular, the rise of personal computing has been considered to be the main factor in the expansion of interest in human–computer interaction (HCI), bringing to this new area professionals from different disciplines and research backgrounds, and integrating and conciliating their different approaches. There have been significant changes with regard to the practice of activities related to information systems, due to the emergence of internet, mobile, and ubiquitous technologies, which have placed HCI research at the forefront of interdisciplinary research in the subdisciplines of computer science.

Even though this multidisciplinary presence enriches HCI research contributions, this diversity means that there is no general consensus about the set of the activities that are part of it (Ferre, Juristo, and Moreno 2003). On the one hand, there are approaches that study how computer technology influences all facets of human beings from a humanistic point of view. Considered part of the subfield called media studies, these approaches have become an autonomous research field separate from HCI research itself,

presenting research mainly in anthropology, ethnography, and journalism-based studies, but also incorporating in some cases archaeological professionals and visions.

On the other hand, there are new areas of knowledge that study the adaptation of computer technology solutions to the intrinsic characteristics of the human being from an engineering perspective, both physically (in areas such as ergonomics, etc.) and cognitively (adapting machine processes to the senses, emotions, and aspects studied in human cognition). This approach is considered today the main focus of HCI research, involving a multitude of studies that have something to contribute to the design, implementation, and evaluation of interactive systems in the context of tasks and works performed by one or multiple users (Dix et al. 2003) and the impact that computer technology solutions have on the users themselves. This is highlighted in a number of distinct research areas:

- The study of human cognition, how humans provide inputs to computers, and how they understand and process the outputs. These studies include user studies and user models, mental and memory models, information processing capacities, reasoning and knowledge formalization, and visual, hearing, or other sense-related studies that can be used as input/output channels for interacting with the computer.
- The study of the interaction channels of the computer (or any technological device with processing capabilities), mainly focused on the interfaces and the different interaction paradigms that can be offered in interaction (graphical, based on natural language, and ubiquitous, based on collaborative interaction, among others). Currently, some relevant research lines are:
 - The development of new techniques and methods for immersive environments, which allow wholly different interactions between the human and computer. Some examples are virtual or augmented reality

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

DOI: 10.1002/9781119188230.saseas0274

(see VIRTUAL REALITY MODELING and AUGMENTED REALITY).

- The creation of new information visualization methods, which focus on the creation and implementation of mechanisms for displaying all kinds of information structures in interfaces, including numerical data (e.g., bar charts, plot charts, pie charts), combinations of such, and geographic (e.g., encoded maps) or time-oriented data (Aigner et al. 2007).
- The study of the incorporation of new advances in HCI to the engineering development process of software systems. This process usually includes specific contributions exploring the practice of engineering, making the process more user-oriented in all phases: from requirement elicitation phases, through user-centered design practices in development and programming of the components, to evaluation phases.
- The study of the implications of new paradigms of HCI in the evaluation and testing of any software product or information system. These approaches create models in different domains that conceptualize the tasks performed by the user with the software system, in order to determine how its adequacy, efficiency, or usability—quality attributes that assess how easy user interfaces are to use (Nielsen 1994)—can be evaluated, among other metrics.

All of these areas share the common goal of understanding the phenomenon of interaction between humans and computers, designing new methods, techniques, and technologies that increase the usability of all types of interfaces and components, and developing new ways to evaluate these developments with experimental studies with real users.

The future of HCI research

Some social factors are determining the current situation and the future roadmap in HCI research. First is the presence of information processing devices and embedded

systems in all aspects of life, such as home appliances and home automation applications, urban applications—creating Smart Cities—and changes in leisure and consumption habits. The network facilities of all these devices enable many of these embedded systems to be coordinated with each other as ubiquitous systems and communicate as a big network with the user. This is usually called the Internet of Things (IoT). The design and evaluation of the mechanisms of interaction with these systems present a major challenge in HCI research.

Especially relevant are social changes, such as relocation of work spaces and the explosion of social networks. These social changes have brought significant advances in some types of device (phones, tablets, smart glasses, etc.), generating new interaction requirements, such as the size reduction of interfaces, the need for adaptive interaction between user and multiplatform applications, collaborative interfaces with interactions that serve many users at once, and the productive incorporation of new developments that change input channels, such as voice-based interfaces and the inclusion of fingerprint analysis or other biometrics interactions in applications.

Another important factor has been the reduction of hardware costs and increased access to computing devices by the general public. This situation has led to new ways to interact with different devices that go beyond one dimension to explore the potentials of multisensory interaction. Good examples are current commercial devices that combine functionalities: bringing together in a single device audio, video, Internet browsing, access to TV channels, videogames, and so on. This phenomenon, coupled with advances in visual representation such as 3D technologies (see IMAGE-BASED 3D MODELING) and new techniques of information collection, allow the emergence of some qualitatively different interaction techniques, such as virtual reality, augmented reality interfaces (see VIRTUAL REALITY MODELING and AUGMENTED REALITY), and other immersive visualizations.

Finally, current trends in HCI argue for incorporating the knowledge of the users, their needs and abilities (see KNOWLEDGE AND INFERENCE), and using this information to replace generic systems with ones that adapt to the user's perception and understanding. Information modeling (see

INFORMATION MODELING), with its advances in semantic representation, allow user modeling as a part of the information system, improving the HCI.

All these lines in HCI research can contribute to create scientific advances that have enormous potential for solving research questions about the past, as well as the present, posed by humanities disciplines. Indeed, the application of advances in HCI research to the humanities forms a distinct subarea of the so-called digital humanities. Thus, humanities researchers, policy-makers, curators, editors, and heritage managers take into account HCI research for identifying, researching, and solving complex past and present cultural-related problems, due to their multilingual, heterogeneous diversity in origin and formats and volume in data, among other aspects of humanities information.

HCI research in humanities

Special mention should be made about the connections between HCI research and research in the humanities, particularly in archaeology-related disciplines (see DIGITAL HERITAGE). As previously mentioned, the widespread use of computational techniques for the resolution of questions in archaeological research about our past has encouraged the implementation of numerous HCI techniques and methods in these fields. Thus, HCI research constitutes an interesting area for archaeologists and other humanities professionals mainly due to (1) the HCI multidisciplinary character which constitutes a vast set of techniques and theoretical frameworks to represent, analyze, generate new knowledge, and disseminate humanities datasets and research results in a more human-intuitive way, for both researchers and professional colleagues and also for implementing new participatory ways in archaeology and humanities studies for all citizens; (2) some of the advances in HCI are currently used in discovering, analyzing, and testing new archaeological and humanistic hypotheses, for instance, helping archaeologists in detecting new archaeological places; and (3) the future of HCI aims at a greater human interaction with all kinds of devices in our daily lives, which makes

archaeology of the future necessarily a combined manual-machine work.

It is noteworthy that, although in most cases these techniques are applied to solve research questions in archaeology, sometimes this application has provided feedback, leading to scientific advances involving contributions in HCI research thanks to the challenges presented to HCI research by the humanistic domains. Good examples are studies of intrinsic characteristics of the interaction of professionals in the humanities, software patterns in humanities applications, and new algorithms that capture and visually represent archaeological objects such as vessels, stratigraphic sequences, and archaeological sites.

In addition, there are a good set of applications of HCI research in humanities fields that use all available HCI techniques and methods for the communication, dissemination, training, and participatory involvement of the general public in specific issues related to archaeology and other humanities disciplines (Morgan 2009). Thus, we can find HCI applications in museums (including completely virtual museums), in educational programs, and being applied in virtualization (Scopigno et al. 2011). The use of immersive environments, including the development of videogames and art structures, using HCI techniques are also good examples of this trend.

What is clear is that the HCI roadmap not only establishes a starting point for solving research questions about our past from a different approach, but also uses HCI applications to improve the dissemination of research results achieved in archaeology and related humanistic disciplines.

Image-Based 3D Modeling

JEROEN DE REU

Ghent University, Belgium

Image-based three-dimensional (3D) modeling can be defined as the 3D reconstruction of a 3D space or object, such as an archaeological landscape, scene, or artifact, by using mathematical algorithms developed in computer vision science to extract using structure from motion (SfM) (Ullman 1979) algorithms and reconstruct using dense multiview stereo (MVS) algorithms (Szeliski 2011) the 3D shape and appearance of scenes or objects from 2D imagery.

Although these algorithms were developed in the 1970s (e.g., SfM), and image-based 3D reconstruction was applied in archaeology in the early 2000s, it is only in recent years that image-based 3D modeling techniques have become increasingly popular in archaeology and heritage studies. This is mainly a result of the democratization of the technology, with new hardware developments and implementation of SfM and MVS algorithms in low-cost and open source software packages. Recent applications include the image-based 3D modeling and analysis of archaeological landscapes, excavations, rock art, artifacts, and even underwater archaeology.

Procedure

To produce an image-based 3D model, one only needs a set of high-quality imagery. Ideally, each photograph is taken from a unique viewpoint, with sufficient overlap with the previous photo (i.e., 60–80% overlap) and each point in the scene is visible from at least three different images. The better the image acquisition strategy and the quality of the imagery, the better the resulting 3D model will be. Nevertheless, research has already shown that “old” imagery (e.g., historic aerial

photographs) can also be successfully used for image-based 3D modeling, given that the structure of the “old” imagery dataset corresponds more or less with the image-based 3D modeling parameters.

The first step in the image-based 3D modeling pipeline, and the most important as it determines the accuracy of the final 3D model, concerns the alignment of the photographs using SfM. SfM allows the reconstruction of the 3D scene or object by moving the camera to several positions around it. During the image alignment, (1) a 3D sparse point cloud is generated representing the geometry of the scene, (2) the relative orientation of the camera positions at the moment of image acquisition is determined, and (3) the internal camera parameters (focal length, principal point location, skew, radial, and tangential distortion coefficients) are computed. Using the computed camera position, one can opt to build a dense point cloud.

Second, the 3D geometry, or surface, of the scene or object is built using dense, multiview stereo- matching algorithms (e.g., Scharstein and Szeliski 2002; Seitz et al. 2006). The output is a polygonal mesh. Besides the computation of the 3D geometry, the color for each model vertex is also calculated and stored as an attribute. During the rendering of the model, these colors (which are an average of the corresponding pixel values from the source photos) are then interpolated for each polygon face, so that each face of the model is filled by a color gradient. When the number of polygons is large, this vertex color approach already provides a very good visual representation of the object's surface. The computation time largely depends on the resolution and the quantity of the used imagery and the level of detail wanted in the geometric model.

Finally, the texture of the object or scene, present in the photographs, can be mapped onto the 3D mesh. The texture atlas is calculated out of one or more source photographs. Each model vertex then stores its coordinate in this texture atlas. During rendering of the 3D object, these coordinates are used to map the texture image

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

© 2018 John Wiley & Sons, Inc. Published 2018 by John Wiley & Sons, Inc.

DOI: 10.1002/9781119188230.saseas0316

onto the 3D model surface. Since the original photographs are mapped onto the geometrical surface, it is possible to provide a very rich texture.

Once the 3D models are scaled or georeferenced, they can be used as an analytical tool to study the 3D shape of the archaeology. The 3D shape can be fully appreciated in a 3D environment (e.g., 3D geographic information system (GIS)), or downscaled to a 2.5D digital surface model (DSM) or a 2D orthophoto. The orthophoto is a geometrically correct 2D image with all the geometric characteristics of a map, while the DSM represents the topography of the uppermost surface of the orthophoto.

Considerations

As with all digital archaeology applications, although image-based 3D modeling has its problems and limitations, these are greatly surpassed by its possibilities. Moreover, computer technology is advancing so rapidly that the limitations are becoming mute (Zubrow 2006). Nevertheless, two limitations are worth discussing here.

First, image-based 3D modeling involves long processing times despite the amount of human time investment being limited to only a few minutes. To successfully produce 3D models, central processing unit/graphics processing unit (CPU/GPU) power and available memory are important. The better these settings, the faster the processing, the larger the number of photographs that can be handled, and the higher the point cloud accuracy and mesh density that can be achieved. Current average-priced computer systems are unable to deliver the highest possible data quality. However, there is no doubt that with new software developments and increasing computer power, the quality of the output, along with the usability and accessibility of the data, will rapidly improve in the (near) future.

Second, the success and accuracy of the image-based 3D modeling is affected by the feature richness of the recorded surface of the object or scene, and thus high-accuracy results are not always guaranteed. Archaeological artifacts in shiny or transparent materials (e.g., flint, glass,

or porcelain) are especially problematic to 3D reconstruct.

Archaeological applications

The application of image-based 3D modeling in various archaeological research projects since the turn of this century has proven that this technology provides detailed and accurate results—up to centimeter and even millimeter accuracies—and that it has the potential to be used worldwide, on a daily basis, at a large scale, and in different environments and conditions, in order to document a broad variety of archaeological landscapes, sites, features, contexts, and artifacts from different chronological eras. As opposed to range-based 3D reconstruction methods, image-based 3D modeling can be achieved with negligible equipment costs and with little to no overheads in the field.

Among other achievements—and in common with other 3D modeling techniques—the most important achievement of image-based 3D modeling is the documentation of the 3D shape of the archaeology, and the possibility it offers to analyze our archaeological data in 3D.

The most popular (and arguably most successful) application of image-based 3D modeling in the field of archaeology can be found in the practice of documenting archaeological excavations. The entire archaeological excavation can be recorded as a 3D space, and the 3D shape of the archaeology can be fully explored and analyzed. With the high accuracy of the methodology, which is frequently more accurate than is probably needed on an archaeological excavation, and with the information about the texture, color, and appearance of the archaeology, present in the photographs mapped onto the 3D model, the 3D modeling results in an accurate, photorealistic 3D reconstruction of the excavation that makes it almost possible to experience and revisit the excavation in a digital environment. The digital environment can be a 2D or 3D GIS that allows full integration of the 3D data with other aspects of the excavation in one spatial environment. If processed during the excavation, the 3D models can be used together with other means of documentation to monitor the field activities

and to plan excavation strategies. Besides the documentation of the 3D shape of the archaeology, another key aspect here is the possibility to record an excavation in a more objective way than with analog methods. Although an excavation can never be fully objective, and, just like with traditional recording techniques, it is the archaeologist who decides on what to excavate and what to document, a more objective documentation of the excavation can be achieved with image-based 3D modeling. The result of the documentation process is, however, a record of the archaeology as it is there, with its 3D shape, its color, and its appearance, and without the interference of the archaeologist's personal interpretation. After the generation of the 3D model, the archaeologist's observations, descriptions, and interpretations are/can be added to the 3D model (as a separate layer). As an important consequence, the 3D model can be (re)viewed, by the excavator(s) or by others, with the archaeologist's interpretation, while an analog recording always represents the archaeologist's personal interpretations. Although this objectivity is a very important achievement for archaeological field research, image-based 3D models cannot be seen as a substitute for traditional descriptive and/or interpretative means of excavation documentation (e.g., drawings). In fact, both methods should be used in a complementary fashion as they provide different "views" on the same subject, both aiding the understanding of the archaeology.

Image-based 3D modeling can be successfully applied on scales much larger than the individual site, encompassing the archaeological landscape. However, unlike light detection and ranging (LiDAR), image-based 3D modeling can only be successfully applied in open landscapes where a vegetation cover is absent. In these open landscapes it allows the 3D modeling of the topographical characteristics of the terrain and detailed analysis of the layout of an archaeological landscape. On this landscape level, the image acquisition usually happens with balloons, kites, or helikites, and more recently with unmanned aerial vehicles (UAVs) or drones. These UAVs hold great potential for archaeology (e.g., to collect aerial images, to map archaeology, or to protect and monitor endangered sites), and they are very suitable to extend the scale of image acquisition for image-based 3D modeling.

With UAVs, larger areas can be covered, and 3D modeled in shorter periods, making UAV-based image-based 3D modeling suitable not only for mapping archaeological sites and landscapes, but also to monitor endangered sites (e.g., modeling of erosion or damage over time).

Similarly, old historic imagery, like military photographs, if suitable for image-based 3D modeling, can be used for the 3D reconstruction of past landscapes. These data are useful to study the evolution of archaeological landscapes through time (e.g., preservation, erosion) or to reconstruct archaeological landscapes that are lost forever (e.g., urbanized landscapes). In this light, image-based 3D modeling has also been successfully applied in the 3D reconstruction of World Heritage Sites, damaged or destroyed in military conflicts (e.g., the Great Buddha of Bamiyan; Grün, Remondino, and Zhang 2004). In these cases, the reconstructions are often made by using tourist photographs. Also, built heritage (or architecture) has frequently been the subject of image-based 3D modeling. Here, the 3D models are made to document and analyze the state of preservation, to detect damage, to model future decay, or to study the construction and architecture of the built heritage.

Image-based 3D modeling has also proven useful in the documentation and study of rock art, both at the level of the detailed study of the individual panel and at the larger landscape level. It also provides a digital copy—a digital means of preservation of this fragile heritage. Probably the most challenging application of image-based 3D modeling in the field of archaeology can be found in underwater archaeology. Its successful application in this difficult underwater environment is another example of the flexibility of use and the great potential of this technology.

On a smaller scale, but no less important, is the image-based 3D modeling of artifacts. While nothing compares to the real artifact, digital 3D copies have proven to be a highly valuable alternative when one is away from the original object, or when it is inaccessible for other reasons. Also, they allow new, simple-to-more-complex metric analyses, allowing detailed shape analysis of the artifacts. Another major advantage of possessing digital copies of artifacts lies in the opportunity to set up a digital reference collection of different types of artifacts. A digital reference collection

can not only be used by researchers as a tool for comparing, identifying, and interpreting artifacts, but also holds great educational potential. Digital 3D reference collections of artifacts can become the new “reference books” for artifact typology, determination, and interpretation, a role currently fulfilled by illustrated textbooks. One can only imagine the research possibilities when entire archaeological excavations, depots, museum, and collections will be available through a 3D library.

Image-based 3D modeling provides an excellent tool for the 3D documentation of archaeology, from the artifact to the landscape level, opening new doors to multidimensional analysis and digital preservation of this heritage.

Imaging

WOLFGANG H. BÖRNER

Museen der Stadt Wien—Stadtarchäologie, Austria

Imaging is the visual representation or reproduction of an object. Imaging is the technique or practice of creating images of otherwise invisible aspects of an object. This includes detecting archaeological remains on the landscape from the air or space, or with remote sensing techniques, visualizing the chemical compositions of archaeological objects, or the examination of objects with noninvasive techniques.

The field of imaging techniques used in archaeology and heritage studies is widespread, including chemical (e.g., multispectral and hyperspectral imaging, neuron imaging), digital (e.g., reflection transformation imaging, three-dimensional (3D) imaging), geophysical (e.g., electromagnetic techniques, ground-penetrating radar, imaging spectroscopy), medical/molecular (e.g., computed tomography (CT) imaging, magnetic resonance imaging (MRI), terahertz (THz) imaging), and thermographic (e.g. infrared imaging, near-infrared imaging) imaging.

The availability of digital tools for the documentation of world heritage has increased exponentially in the decades since the 1960s. Equipment costs have come down while, simultaneously, the imaging processing speed has gone up. Tools and techniques, especially visualization techniques which were once reserved for the best-funded projects, have been adopted by a broader segment of the archaeological community.

Imaging methods use measurement data to visually represent archaeological objects in order to detect and delimit their characteristics. Measurement data, or information derived from the measurements, is spatially resolved and is made visible through the assignment of brightness or color values. Imaging methods are applied in almost every natural scientific field, including

medicine, archaeology, material inspection, and remote sensing, to name a few.

The word “imaging” was already in use as early as the fourteenth century by the German mystic Heinrich Seuse in his “Vita” where he uses the terms “*bildgebender wise*” (imaging manner) and “*bildgebender glichnus*” (imaging parable) (Seuse 1907, 3.3, 191.1).

The oldest and simplest imaging tool is the camera obscura or the pinhole camera (Renner 1999). It was in use at the end of the thirteenth century by astronomers for the observation of sunspots. Telescopes and microscopes are other imaging tools and these were developed around 1600.

The discovery of X-rays, development of the computer, and invention of the digital still camera allowed for the broad use of imaging technologies. These started in the field of medicine during the 1970s and rapidly spread to other scientific disciplines.

X-rays were first used in 1898 by the archaeologist Sir Flinders Petrie to image the inside of an Egyptian mummy, just three years after their discovery by Wilhelm Roentgen. Petrie was followed by Elliot Smith and Howard Carter in 1904 (Hughes 2011, 57). Medical X-ray CT scanners became available in the early 1970s and were a gigantic leap in diagnostic imaging. With the CT scanner, it was the first time that 3D images of the body could be produced. The first CT scan of a mummy was performed in 1977 by Derek Harwood-Nash in Toronto, Canada (Harwood-Nash 1979). CT imaging is also used in the study of clay and ceramic archaeological objects, metal works like coins, and other organic remains.

MRI was invented by Paul C. Lauterbur in 1971. MRI is not frequently used in archaeological studies because the scanned object needs to have significant moisture content, which is generally not the case for archaeological artifacts (Hughes 2011, 60). In 2009, THz imaging was performed on parts of a mummy in conjunction with CT and was found to provide more soft tissue information than CT, although at lower spatial resolution.

The 1960s saw the beginning of archaeological computing and processual ways of thinking. Invention of the microprocessor in 1971 and the subsequent rapid development of microprocessors have been breath-taking and are encapsulated within the generally acknowledged Moore's Law. In the late 1980s and 1990s, the development of graphics, visualization, multimedia, and integrated software products also paved the way for imaging technologies.

Since its very first applications, photography has striven for the accurate reproduction of reality. The first photograph ever produced was in 1826 by the Frenchman Joseph Nicéphore Niépce. The first digital image was produced in 1920, by the Bartlane cable picture transmission system. British inventors Harry G. Bartholomew and Maynard D. McFarlane developed this method. Steven Sasson, an engineer at Eastman Kodak, invented and built the first electronic camera using a charge-coupled device image sensor in 1975. It was the mid-1980s before electronic cameras began to be introduced to the commercial market. Storage was the problem that needed to be overcome for widespread adoption. Some of the first digital cameras recorded images to cassette tapes, and even into the 1980s most used floppy disks. The first digital cameras for the consumer-level market that worked with a home computer via a serial cable were produced in the mid-1990s. In recent years, the quality and the resolution of digital cameras and digital video

cameras has reached a level that they can be used for special digital imaging projects such as airborne photography and satellite imaging.

Information Modeling

CÉSAR GONZALEZ-PEREZ

Institute of Heritage Sciences, Spanish National Research Council, Spain

Context and overview

Science uses models for multiple purposes, such as describing, explaining, and communicating things. The concept of model is old, dating back to at least the seventeenth century, accompanying the prelude of modern science. Since then, a model has been considered to be an artifact constructed to represent something in a meaningful way. For example, a cardboard replica of a planned house development created by an architect in order to study and decide on the lighting and overall appearance is a model; similarly, a Harris matrix that an archaeologist draws on paper in order to document, communicate, and reason about the stratigraphy of a place is also a model. The notion of model as representation has several consequences. First, a model represents something. For example, a map represents a portion of the territory, or a Harris matrix represents a stratigraphic sequence. Second, a model provides a simplified view of the represented subject. For example, the lines and shapes on a map are much simpler than the real territory, and the boxes and connectors on a Harris matrix capture vital information about relative location of each stratigraphic unit, but discard other aspects such as their size or chemical composition. In this regard, the *purpose* when creating a model determines what details are retained and which ones are discarded; for this reason, two models of the same thing can be very different if they pursue different goals. For example, the models of the human body that are often employed by doctors and anthropologists are quite different. Finally, a model allows us to reason on the representation, and then apply the conclusions to the modeled subject. For example, measurements carried

out on a map are expected to be valid on the terrain.

An information model is a model that is composed of information, rather than cardboard or ink on paper. Information models, like any other models, represent something by simplifying it and allow us to reason about it by looking at this simplified view, and then apply the results to the original thing. However, since information models are made of information, it is often difficult to convey the model in a straightforward manner, because information, as such, is not visible but abstract. For this reason, information models are usually depicted on paper or a computer screen in order to be useful. For example, the collection of deposits, interfaces, and other strata at a particular site, when observed by an archaeologist, can be conceptualized as a network of interlinked stratigraphic units in the archaeologist's mind. Then, they can draw a sketch on their notepad representing these ideas. There are two representation processes going on here: from the physical entities observed in the world to the network of stratigraphic units and links in the archaeologist's mind, and from these to a collection of boxes and lines sketched on a sheet of paper. Both the first and last entities in the chain, namely the actual strata and the ink on paper, comprise physical things. The intermediate entity, namely the conceptualization in the archaeologist's mind, is an information model.

Information models are more abstract than data and less abstract than knowledge, according to Ackoff's hierarchy (Ackoff 1989). Data are usually understood as being composed of simple and uninterpreted quantities or qualities such as numbers, texts, or images. Information builds on data by adding a sender and a meaning to be conveyed; in other words, information is about telling others about things by using data and for a particular purpose, and for this reason it involves a particular interpretation. Knowledge, in turn, is related to true justified beliefs, which are constructed on information and usually conveyed through it. In this context, information models work by capturing and conveying the necessary

data to the right people in order to generate new, or revise existing, knowledge (see KNOWLEDGE AND INFERENCE).

Information models can be useful in relation to five major purposes. First, they can help people *explore* areas of the world that are not well understood. For example, you can try to represent the same archaeological evidence by selecting different details to capture, so that you try various approaches to describe the same reality and see how well each one works. Second, information models are useful to *document* things or phenomena for later reference. Usually, archaeological works such as excavations entail the complete destruction of the things being studied and, for this reason, having a good model of these things is crucial. Third, models are useful to *communicate* information to others. For example, an information model can be very useful when archaeologists work together with specialists from other disciplines such as anthropologists or architects, because it helps bridge the gap between the different mindsets and working styles of the different disciplines, and establishes a lingua franca that everyone can understand. Fourth, models are useful to help people *design* tools and techniques for their work. For example, a good information model is an excellent basis on which to develop field survey forms or database structures to store and manage the recorded data. Finally, models are useful to make information and tools *interoperate* with others. People naturally tend to work in a manner that is best adjusted to the task at hand; however, they often want to interchange information with others, compare results to multiple sources, or even integrate information into larger corpora. For this to happen, information needs to be clearly and unambiguously expressed, as it usually is when employing an information model.

What information models can express

Information models can express almost anything about anything. They accomplish this by addressing very abstract kinds of statements that can be made in natural language. First, information models can express *existence*, that is to say, they can state that something exists. For example, in “There are five Iron Age sites in this region,” existence of five sites is being stated. Second,

they can express *identity*, that is, whether two things are the same or not. For example, in “This place is where ore was extracted by the people of that settlement,” a statement is being made that “this place” and “where ore was extracted” are the same thing. Third, information models can express *predication* or, in other words, the assignment of a property or role to an entity. For example, in “This site covers 8,500 square meters,” the value of *8,500 square meters* is being assigned to the site’s *surface area* property. Fourth, information models can express *classification*, that is, they can assign a category to an entity. For example, in “This is a fragment of a bell beaker,” something is being classified as a fragment of a particular kind of vessel (see ARCHAEOLOGICAL CLASSIFICATION). Finally, they can express *subsumption* or, in other words, the fact that some categories subsume or encompass other categories. For example, in “A hillfort is a kind of settlement,” the *settlement* category is being stated to subsume or encompass *hillfort*.

In this manner, an information model is a collection of information elements and relationships between them, so that its content and structure represent some relevant portion of the world.

Technical aspects

Natural language allows us to express almost anything, but it usually involves a large degree of ambiguity and underspecification. Although natural language is, and will certainly remain, a crucial mechanism for representation in science, information models can do better in specific situations that require a higher degree of expressive accuracy. In fact, information models are usually constructed by using a particular *modeling language*, that is, a set of rules and conventions that determine how things are expressed. A modeling language, like a natural language, involves a lexicon, grammar, and some semantics. The lexicon is the set of “words” or basic language units that people can use. For example, when constructing a Harris matrix, two kinds of language units are often used: stratigraphic units and links. The grammar comprises a set of rules that must be obeyed when putting lexicon elements together in order to compose meaningful “sentences.” For example, in a Harris matrix, one stratigraphic

unit can be connected to another through a link, but links cannot be connected to other links. The semantics of the modeling language is the collection of relationships between the mentioned “words” in the lexicon and the things in the world that they refer to. In the case of Harris matrices, semantics tells us that labeled boxes correspond to specific deposits, interfaces, or other strata, and links correspond to specific sequencing situations between them.

Modeling languages and, as a consequence, information models allow people to represent the world according to two different viewpoints, by focusing on either entities or categories. The first one refers to the specific entities that can be observed or imagined. For example, an archaeologist may create an information model describing the set of ramparts, ditches, walls, and other structures found during the excavation of an Iron Age hillfort. This model would be describing that specific hillfort, and each element in the model would correspond to a specific rampart, ditch, or wall in the world. Model elements that stand for specific entities in the world are called *instances*. However, there is a second way to represent the world, namely, in terms of the categories of things that are observed or expected, rather than the very specific things themselves. For example, an archaeologist planning to study how people living in different hillforts exploited their immediate environment and traded between them may create a model that describes the different activities that are expected to be found, such as mining or fishing, and how these activities can be related to hillforts. This model would not be describing any particular hillfort or activity, but the fact that, in general, activities of different kinds can be associated with hillforts and these, in turn, can be related to other hillforts in relation to activities. In other words, this model would be describing the world in terms of categories (*hillfort*, *fishing activity*, *mining activity*, etc.) and connections between them. Model elements that stand for specific categories are called *types*.

Instance models are useful to describe a specific thing or phenomenon, such as a particular site, feature, society, or cultural process. Type models, on the other hand, are useful to describe general patterns that are observed or expected, such as the ways in which features and finds are

related, what finds appear where, what processes occurred in what places and when, or how people enjoy visiting site museums. Type models, being based on categories rather than specific entities, involve a larger degree of subjectivity, and may be more difficult to develop. However, and since they are much more encompassing than instance models, they can potentially be useful to many more people and in multiple situations.

Furthermore, instance and type models are strongly connected through *conformance*. When an instance model is created to describe particular entities in the world, the author can state, as part of the model, how each of the represented entities is categorized. In this manner, a connection is established between the instance model being created and a previously existing type model that describes what categories of things are expected. For example, when describing a particular lithic artifact as part of the instance model, information may be included that states that the thing being described is classified as a *LithicArtifact*. In order for conformance to work, and for these data to be meaningful, the *LithicArtifact* category must be present in a pre-existing type model. In a situation like this, it is said that the instance model being created conforms to the mentioned type model. Often, type models are created first, as a rough approximation to what kinds of things are expected to exist in a particular place or situation, and then conforming instance models are constructed to describe specific explorations or perspectives on the place or situation. For example, a research group may agree on a type model describing the major categories of things in the archaeological record that they usually work with, such as *Place*, *Site*, *Artifact*, or *Hillfort*. Then, each project or individual archaeological action creates an instance model that conforms to this type model in order to document and communicate what was found.

Finally, information models, being made of information, are invisible, so they must be represented visually in order to be shared or discussed. For this purpose, a *graphical notation* is often employed that establishes some rules on how to depict each type of model element. When represented graphically, information models usually take the form of diagrams composed of boxes, lines, and texts.

History of information modeling

As practiced today, information modeling in archaeology is based on two different streams of research that took place over the last few decades: conceptual modeling and ontology engineering. These two fields have been converging for some time and in many respects overlap greatly. Conceptual modeling appeared within the software engineering discipline in the 1980s as a manner to represent the structural and functional requirements of stakeholders in terms of concepts, as well as the software systems to be developed from these requirements. The major aim of conceptual modeling was to be highly expressive and as accurate as possible in its descriptions, and a large body of work was developed over the 1990s and 2000s with this purpose in mind. Languages such as unified modeling language (UML), initiatives such as the Object Management Group's (OMG) model-driven architecture (MDA), and toolsets such as Eclipse helped further this field. Today, conceptual modeling is pervasive in the software engineering industry. However, conceptual modeling and software are linked only for historical reasons, and an increasing number of projects are employing conceptual modeling in areas different to software such as business organization and genomics.

In parallel, ontology engineering emerged within the artificial intelligence community starting back in the 1970s. The major aim of artificial intelligence was to create machines that could think like humans; for this purpose, some authors focused on studying how portions of reality can be represented inside a computer so that automatic reasoning can be carried out on them (see ARTIFICIAL INTELLIGENCE). As opposed to conceptual modeling, the major focus here was not expressivity or accuracy, but allowing computers to use the represented information to perform automatic reasoning. Significant innovations were made over the 1990s and 2000s, including technologies such as CycL, a computer language based on first-order logic that could manipulate a "knowledge base" and carry out reasoning on its contents. Eventually, models constructed under this line of work were named "ontologies," in reference to the branch of philosophy that studies what things exist and how. Since then, ontology engineering (see

SEMANTIC WEB AND ONTOLOGIES) has been an active area of research, especially in the context of the so-called semantic web. The semantic web is the idea, pioneered by World Wide Web inventor Tim Berners-Lee, that the information available on the web should be processable by machines in addition to humans. In this context, having "ontologies" that describe specific realms of reality in a machine-oriented manner is crucial. The World Wide Web Consortium (W3C) has developed this idea into technologies such as linked open data, the Simple Knowledge Organization System (SKOS), and Web Ontology Language (OWL) (see SEMANTIC WEB AND ONTOLOGIES).

Conceptual modeling and ontology engineering, although coming from different backgrounds, pursue very similar goals. Recently, some authors have argued that ontologies are in fact a particular kind of conceptual model, and that both can be easily aligned and reconciled. Also, recent works in conceptual modeling have emphasized an ontological approach, and recent works in ontology engineering have moved closer to conceptual modeling. In this manner, information modeling in archaeology can draw from both fields without major issues.

Current and future developments

Under the umbrella of the digital humanities and, in particular, digital archaeology, many research lines are actively working on archaeological information modeling. One of the most active areas relates to the creation of ontologies (or information models) of the archaeological record and associated things. A good example is ISO 21127 (ISO 2014), also known as the CIDOC Conceptual Reference Model (CRM). This is a collections-oriented type model that describes everything related to heritage areas, which has been standardized by ISO. CIDOC CRM-English Heritage (EH) is an extension to the original CIDOC CRM that addresses archaeological processes. A second relevant example is the Cultural Heritage Abstract Reference Model (CHARM) (Incipit 2016a), a type model that also addresses heritage as a whole, but which is based on an extensible framework so that adjusted particular models can be created for specific projects. Using

CHARM, different projects or organizations can employ different conceptualizations of the archaeological record (and, as a consequence, different models), but still maintain the necessary interoperability between them.

A second area of active research is that of the development of specific tools and online services based on archaeological information models. Large infrastructure projects such as Europeana or Advanced Research Infrastructure for Archaeological Dataset Networking in Europe (ARI-ADNE) are providing aggregated datasets that can be queried online and integrated with others.

Finally, a challenging and emerging area of research is that of improving the representation process itself. Archaeology, like other disciplines in the humanities and social sciences, involves “soft” issues such as subjectivity, temporality, and vagueness that are rarely considered by the engineering-oriented disciplines from which information modeling has emerged. To improve the existing modeling mechanisms with new features, research is being carried out in the area of modeling languages. A significant example is ConML (Incipit 2016b), a conceptual modeling language that incorporates explicit temporality and subjectivity management as well as some support for ontological and epistemic vagueness.

Infrared Reflectance Spectroscopy

ANNA SANDAK

CNR-IVALSA—Trees and Timber Institute, Italy

JAKUB SANDAK

InnoRenew CoE, Slovenia; CNR-IVALSA—Trees and Timber Institute, Italy

Introduction

Infrared spectroscopy is a field of science exploring the interaction of infrared radiation with the matter being investigated. The infrared radiation itself is a part of the electromagnetic spectrum located between visible light and microwaves, covering wavelengths between 700 nm and 1 mm. Infrared spectroscopy has proven its greatest applicability in several scientific fields, including archaeology (see INFRARED ABSORPTION SPECTROSCOPY (IR, FTIR, DRIFT, ATR)). This technique permits chemical composition assessment, the identification of materials, and authentication and provenance recognition, among other capabilities. The measurement is rapid, nondestructive, and highly informative. If properly configured, infrared spectra include both qualitative and quantitative information, assessed from any kind of sample (organic, inorganic) in any state (liquid, gaseous, solid), and presented in a small amount (milligrams) (Stuart 2004).

Theoretical background

The infrared radiation emitted into the sample can be transmitted, absorbed, reflected, and/or scattered. Absorption occurs when a specific molecule exposed to such radiation excites to vibration in covalent bonds, matching the radiation frequency and the natural vibrational frequency of the molecule. In principle, only molecules with a change in the dipole momentum absorb infrared, thus only specific functional

groups are detectable in a spectrum (such as amides in the silk proteins, phosphate in bones, hydroxyl groups in cellulose, etc.). The pattern of absorption is highly selective and depends on the molecular configuration of the measured matrix as well as on the properties of the stimuli (radiation) applied. The scatter is not related to the chemical composition of the sample, but to the physical arrangement of molecules. The pattern of the light scatter relies, therefore, on particular properties such as density, crystallinity, and size of particles.

The overall infrared band is subdivided into three regions corresponding to the near-infrared (NIR), mid-infrared (IR) and far-infrared (FIR). The IR region is sectioned into short-wavelength infrared (SWIR), mid-wavelength infrared (MWIR), and long-wavelength infrared (LWIR). Diverse characteristics of matter can be assessed when measuring spectra in each region, with the functional group region and fingerprint region included in the mid-infrared range. Combination bands and overtones of fundamental vibrations are located within the near-infrared.

The light transmitted through the sample is analyzed with conventional infrared spectroscopy, in contrast to reflectance spectroscopy when only part of the light reflected from the sample surface is assessed. Three modes of reflection occur in the majority of materials: specular, diffuse, and attenuated reflectance. In practice, all three of these take place simultaneously, although with different contributions (Khoshhesab 2012).

Attenuated total reflectance (ATR) occurs when a beam of radiation passes from an optically denser medium (high refractive index) into a less-dense medium possessing a lower refractive index. The total internal reflection of the light at the interface zone creates an “evanescent wave” that penetrates the subsurface of the sample. Crystals with a high refractive index and excellent infrared light transmittance, such as diamond, zinc selenide (ZnSe), or germanium (Ge), are usually used as internal reflection elements. The evanescent wave is absorbed (attenuated) when the sample is placed in close

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

DOI: 10.1002/9781119188230.saseas0327

contact with the crystal. The ATR technique is an optimal solution for assessing thick samples strongly absorbing infrared. It provides similar spectra to that of transmittance, with the exception of slightly higher absorption at longer wavelengths.

Specular reflectance occurs when the major part of the light is reflected at the same angle (to the normal) as incident radiation. The specular reflectance measurement provides excellent qualitative data and may be used for analysis of organic and inorganic samples having large, flat, reflective surfaces. In any case, some of the energy that passes through the surface layer is absorbed into the bulk of the sample, and then reflects from a substrate below. It is especially evident in the case of measuring thin samples or films placed on a mirror, when combined reflection and transmission become transreflectance. The reflectance/transreflectance spectra differ, therefore, from those recorded in a pure transmission. The Kramers-Kronig transformation is used to remove effects of dispersion and to permit qualitative comparison of spectra.

The infrared radiation reflected from rough surfaces, defined as “Kubelka–Munk” reflection, is analyzed with *diffuse reflectance spectroscopy* (DRS). This technique is used for the characterization of solid samples or powders (both organic and inorganic) having a coarse surface such as textiles, wood, bones, or paper. Particle size, homogeneity, and packing density of powdered samples highly influence the quality of spectrum; therefore special attention should be directed to sample preparation and presentation. The scattering phenomenon is more pronounced at shorter wavelengths. Thus, diffuse reflectance measurement in the near infrared range (DRIFTS) is most commonly utilized. Similarly, the infrared penetration depth depends on the light wavelength and optical density of the bulk material, varying between fractions of micrometers to a few millimeters.

Instrumentation suitable for archaeology

Infrared spectroscopy is a relatively well-established technology, and dedicated spectrometers have been commercially available since the 1940s. Today, several options for infrared

spectra acquisition exist in all ranges, with the majority of instruments tuned to sense near- and mid-infrared frequencies. The most important practical considerations when selecting an optimal spectrometer are to define the expected rigidity of the sensor (dedicated to laboratory or in-field applications), required spectra range, resolution, sensitivity, and scanning time.

Fourier transform (FT-IR and FT-NIR) spectroscopy provides superior quality of spectra in a relatively short measurement time. However, the application of these instruments is usually limited to the laboratory environment because the optics implemented (e.g., interferometers) are very sensitive to mechanical vibration. The raw result of measurement is a time-resolved interferogram, converted into a spectrum with a fast Fourier transform (FT). FT spectrophotometers operating in the NIR range are frequently equipped with fiberoptics or an integration sphere.

Dispersive fixed grating diode array (DA) and linear variable filter (LVF) spectrophotometers have small size, a lightweight/compact design, and do not contain moving parts. In combination with a short scanning time, both techniques are alternative solutions for in-field measurements. The drawbacks are the limited spectral range, sensitivity, and lower resolution when compared with FT spectrophotometers.

Hyperspectral imaging (HI) (see MULTI-SPECTRAL AND HYPERSPECTRAL IMAGING OF ARTWORKS) allows the acquisition of spatially resolved spectra, and this is advantageous for the characterization of heterogenic materials or chemical mapping (see CHEMICAL MAPPING) of complex sample surfaces. As an alternative, multispectral imaging (MI) is used if fewer than ten images at diverse spectral bands are acquired at once. Placing the HI or MI cameras on drones or aeroplanes allows the spectral imaging of large areas in a relatively short time without any disturbance of investigated artifacts or archaeological sites (see SATELLITE HYPERSPECTRAL AND MULTISPECTRAL IMAGING). Hyperspectral imaging of archaeological objects might also be an alternative during artifact assessment, since every pixel contains spatially resolved chemical information.

Result of measurement

The spectrum is the usual result of the infrared measurement. It corresponds to an array of numbers in which the amount of light absorbed/reflected/transmitted is associated with the incident light wavelength. The spectrum

can be plotted on a graph where the ordinate corresponds to the absorbance and the abscissa to the wavenumber (cm^{-1}) or light wavelength (nm). Depending on the measurement range, a spectrum might include information related to the fundamental vibrations (IR), overtones (NIR), or combination bands (NIR). The most

Table 1 Properties of diverse archaeological objects assessed with reflectance infrared spectroscopy.

<i>Type of object</i>	<i>Property</i>
Bones, ashes	Distinguish unburned from burned bone Cremation temperature and duration Diagenesis
Food residues	Detection of food remains and organic components in sediments Identification of di- and triglycerides from meat fats, nut oils, maize, and a variety of plants
Textiles	Recognition of nature of fibers and dye types
Wood	Prediction of cellulose and lignin content Assessment of decay type Estimation of waterlogging conditions
Paper and parchment	Evaluation of preservation state Type and provenance Ink composition
Pottery, ceramics	Identification of traces of the mineralogical composition present in ceramics, pastes, temper particles, binders, glazes, slips, paints, and pigments Identification of crystalline minerals and pseudo-amorphous fired-clay Clay provenance Firing temperature
Porcelain	Pigment and glaze composition Firing temperature and conditions Analysis of tints and shades of the blue coloration Oxidation states and relative amounts of cobalt, iron and manganese
Frescos	In-situ pigment identification Discovery of discolored/lower layers
Inks, binders, coatings, and paintings	Differentiating between the classes of natural organic materials for conservation purposes Actual decrease of the components on leaching of the paint film Loss of carboxylic acids and triglyceride ester linkages Recognition of ink types Decisions regarding conservation treatment
Gemstones	Recognition of mineral type Sourcing and provenance
Amber	Distinguish variety and provenance
Sediments and deposits	Identification of type of deposits Susceptibility to severe diagenetic alteration
Stone tools	Identification of animal micro-residues on stone tools Chemical signature

important limitation of infrared spectroscopy is the very complex nature of the raw spectra and consequent necessity for use of sophisticated mathematical methods for data mining (see *MULTIVARIATE ANALYSIS*). Chemometrics, the science of extracting information from the chemical system, is most frequently used for interpretation, exploration, classification, and regression analysis of the infrared spectral data.

Visual interpretation is most effective in the case of IR spectra, especially within the fingerprint region ($650\text{--}1750\text{ cm}^{-1}$). Several existing band assessment tables may assist interpretation; however, development of custom knowledge bases is indispensable in most real cases of archaeological studies. This is because many archaeological materials are composites of several constituents (e.g., oils, resins, fats), and so their spectral signal is a complex superposition of individual components. Furthermore, several deterioration processes (see *DETERIORATION*) take place during artifact deposition as well as when post-excavation and/or post-depositional contamination occurs.

Pre-processing of infrared spectra is frequently used to minimize variability within the signals and to assist the data interpretation. Averaging, smoothing, derivatives, normalization, baseline, or scatter correction are routine, and are the protocols most ordinarily implemented.

Basic exploratory analysis allows recognition of a hidden structure within large datasets. Principal component analysis (PCA) or cluster analysis (CA) allow visualization of natural clustering of the spectral data. The infrared spectra are a highly useful source for quantitative analysis of measured materials. Partial least squares (PLS), multiple linear regression (MLR) and principal components regression (PCR) are methods commonly used for numerical modeling and prediction (see *PREDICTIVE MODELING*). In any case, the model is assumed to be reliable only after a proper validation procedure. The independent test set validation is considered as superior and should be applied for testing of model robustness.

Application examples in archaeology

Proper spectroscopic data analysis allows the determination of an artifact's conservation state, its transformation in time, as well as deterioration rate caused by biotic and abiotic degradation processes that include decay, weathering, water-logging, thermal degradation, and crystallinity change (Margalis 2014). Several successful applications of infrared reflectance spectroscopy within archaeology are reported in the literature (Table 1), covering various types of objects, measured both in the field and in the lab, during excavation, intervention, and/or conservation.

Limitations of infrared spectroscopy

While possessing several advantages, infrared spectroscopy also has important limitations. Not all of the chemical-physical properties of the material can be directly assessed with infrared techniques. For this reason, it is extremely important to ensure the proper preparation of the calibration and validation datasets covering the whole range of the measured property variation. The process for the correct implementation of spectroscopy is very complex, starting from appropriate problem definition, experimental design, descriptive sampling, instrument selection and configuration, and ending with trustworthy chemometric analysis. Once developed, models need to be constantly validated and updated (Sandak, Sandak, and Meder 2016).

Isovist Analysis

AKKELIES VAN NES

Western Norway University of Applied Sciences,
Norway; Delft University of Technology, Netherlands

Visibility can be defined as the extent to which the spaces between walls and obstacles are visible to one another in excavated towns or buildings. Since the millennium, the space syntax method, developed by Bill Hillier and colleagues at University College London, has been applied to archaeological studies in order to explore this property. This method consists of calculating the various degrees of visibility of the built environments' public spaces and spaces inside buildings.

For analyzing built environments, space syntax consists of four things. First, it gives a *concise definition* of urban space. Second, space syntax is a family of techniques for *analyzing* built environments as the networks of space formed by the placing, grouping, and orientation of buildings. Third, in the field of archaeology, space syntax offers a set of techniques for *observing* how these networks of space relate to functional patterns such as the dispersal of functions, area differentiation, and the location of various identified artifacts. Fourth, based on empirical results, space syntax is a set of *theories* about how urban space networks relate in general to the social, economic, and cognitive factors that shape them and are affected by them. Underlying this is the *theory of the natural movement economic process* which states that the spatial configuration of the built environment influences the movement pattern from everywhere to everywhere else and the location pattern of economic-related activities (Hillier et al. 1993), and the techniques have been applied to a large number of cities in different parts of the world. In this way, a substantial database now exists of cities that have been studied at some level using space syntax (Hillier et al. 2007).

The space syntax method offers three basic elements for analyzing visibility: convex space, isovist field, and axial line (Figure 1). The main

assumptions behind these elements are that (1) human beings move according to axial sightlines; (2) they interact in convex spaces; and (3) they see changeable panoptical views when moving around in the built environment.

A *convex space* is defined as a space such that "all points within that space can be joined to all others without passing outside the boundary of the space" (Hillier 1988, 68). It is mostly used for studying the occupation of various functions and place-bound human activities such as standing and sitting. Convex maps are used for analyzing buildings and the public spaces between a group of buildings in neighborhoods or smaller villages. More recently, point depth and all-lines analyses have replaced the convex space analysis (see below).

An *isovist field* represents the panoptical view a person has from a given point in an urban space. It is used for orientation or way-finding in the urban fabric. According to Benedikt, an isovist is "the set of all points visible from a given vantage point in space and with respect to an environment" (Benedikt 1979, 47). It visualizes the panoptical view from the viewer from a particular standing point in a built environment, where borders are defined by walls and freestanding objects such as trees, bushes, and statues. When moving around, the shape and size of the isovist change. It is thus possible to visualize the sequence of scenes or panoptical view arrows from particular points along the movement routes.

The 180-degree isovist field shows the panoptical view when entering a place, while the 360-degree isovist field shows the panoptical view when turning around on the spot. Consider person A entering a place, as shown in Figure 2. A is a visitor and wants to have an overview over the area. Behind a building, person B is hiding from person A. An isovist field of 180 degrees is made for visualizing A's direct view. Person B has to know that A cannot see him or her. Therefore an isovist field of 360 degrees is made from B's position. The isovist field for person A is larger than that for person B, because person A is standing at a place with a large overview. Person B is

Figure 1 Three basic elements for analyzing visibility.

hidden behind a building, which affects his or her isovist field.

Point depth analyses show the degree of visibility from every point to all others in the public spaces of a neighborhood. This method is useful to test out where the most visible and less visible areas are in urban squares with freestanding objects. In practice, all public spaces in a built environment are rasterized by a grid. Each point for the visibility analyses is taken from the center of each cell's square. How integrated each point is in relation to all other points is calculated. Obstacles like walls, fences, and trees contribute to increasing the visual relationships between various cells.

An *axial line* represents the longest *visual sightline* in an urban space, and also represents the way human beings move in lines through the urban street network. It is the basis for analyzing degree of spatial integration. Direction change analyses measure the *to-movement* potential, while angular deviation analyses with metrical radiuses measure the *through-movement* potential. Each of these two types of relational pattern can be weighted by three different definitions of distance. The *metric* distance measures a town's street and road network as a system of shortest paths, while the *topological* distance calculates a town's street and road network as a system of fewest-turn paths. Finally, the *geometrical* distance calculates a town's street and road network as a system of least angle change paths. Each type of relation can be calculated at different radii from each street segment, defining radius again in terms of either shortest, fewest turns or least angle paths (Hillier and Iida 2005, 557–558). Together these spatial measurements can show the degree of spatial inequalities on various scale levels, and the results are useful

in gaining understandings of socioeconomic activities based on the information encoded in the physical form of excavated towns or past built environments.

Figure 2 shows a point depth and all-line analysis. The large open space in the square is the most integrated one (colored in black), while spaces behind buildings and trees are the most segregated ones (colored in light gray). An axial analysis carried out on Pompeii's street network revealed that shops were located along the highest integrated streets.

The degree of visibility between buildings and streets can also be measured. Degree of intervisibility between entrances influences the degree of social control. In practice, the number of inter-visible doors and windows is divided by the total number of houses in each street segment. The percentages can be grouped in 100, 75, 50, 25, and 0 percent intervisibility for each registration. Thus, two buildings with two entrances facing towards each other indicate 100 percent intervisibility of doors. Conversely, a street segment with a high density of entrances on only one side of the street segment is defined as 0 percent intervisible. These values can then be interpreted in order to shed light upon socioeconomic life. For example, a high density of entrances directly facing a street segment on only one side can be an indicator of an active street life, yet one lacking in social control (Van Nes and López 2010).

When applying space syntax to excavated sites it is important to clarify the chronological context of the analysis. Often, changes to the street network and buildings through time are layered upon each other, like, for example, Ostia (Stöger 2009). Some layers might be lost, while others are highly visible. While archaeologists aim to understand how the various spaces on an excavated site

Figure 2 Examples of isovist fields, point depth, and all-lines analyses.

were used through the identification of excavated artifacts, visibility analyses enrich this by giving indications on the degree of street life, location of economic activities, and degree of social control between buildings and the spaces between them.

The results of the application of visibility analyses on excavated towns and buildings show many similarities with present built environments. When a street segment is on a spatially integrated main route, more buildings are directly connected to streets, and the entrances on each side of the street are intervisible to one another. Conversely, the further away a street segment is from a main route, the more building entrances are hidden away from streets and the degree of intervisibility between them is lower. The further

away from main routes, the more silent street life tends to be.

Take, for example, studies of Pompeii. Here shops and bakeries are seen to locate in the most integrated streets, with a high number of connections to other streets in a short metrical distance. Likewise, these streets have a high density of intervisible entrances connected to them. Religious buildings and political institutions locate themselves one direction change away from the most integrated streets. They are seldom located along or at the end of the integrated main streets. Brothels locate in side streets metrically close to the integrated main streets. In contrast, workshops, taverns, and drinking places are located along the main streets and in side streets close to

main streets. Conversely, the public baths, theatres, inns or hotels, sport, and leisure facilities are spread throughout the town's street network. The challenges for applying visibility analyses on excavated sites are as follows: in the first instance, a reconstruction of a town's street pattern must be available. Second, precise mapping of walls and entrances provides the basis for measuring a street's degree of intervisibility. In cases where it is impossible to ascertain a site's street network, visibility analysis between buildings and streets can to some extent give spatial indications as to how lively or quiet a street probably was in the past. To some extent, various visibility analyses can also indicate functions in adjacent buildings where identifiable artifacts are lacking.

Laser Scanning

JAMES MILES

Archaeovision, UK and Estonia

Laser scanning provides archaeology with a high-speed process for the acquisition of three-dimensional (3D) spatial data. The technique provides surface-based 3D measurements of any small- or large-scale, complex, irregular, standard or nonstandard real-world scene. The resulting data are visualized through the production of point clouds, with the final results depicted as line drawings, computer-aided design (CAD) models, 3D surface models, and video animations (Boehler and Marbs 2004, 292), acting as an enhanced communication tool that has the ability of visualizing real-world objects in 3D space. It is the most effective way to quickly obtain data from the observed object and it enables measurements of areas that were unable to be collected previously, such as through hand-based drawings or total station surveys (see TOTAL STATION).

Laser scanning data are collected through a systematic regular grid pattern, whereas recording methods such as photogrammetry (see DIGITAL PHOTOGRAMMETRY) concentrate on an object's discontinuities and representative structures (Grussenmeyer et al. 2008, 215). Through the collection of multiple scan positions, overlapping datasets are produced, and through a systematic recording methodology, an overall model is produced.

Three different types of laser scanning technique exist: triangulation or range laser scanning; time-of-flight laser scanning; and phase laser scanning. Each method captures and processes the recorded objects in different ways. These three techniques follow the same methodological approach of pre-processing the data via scanner operation and examining the object or site in question; recording the objects; stitching the multiple scans together; and processing the results. Although similar methodologies are used, differences can be seen in each.

Triangulation or range laser scanning is a technique that is more suited to the recording of small objects (less than 1 m). The technique works by projecting a light spot or line onto the surface of an object. The position of the spot or line is recorded through a charge-coupled device (CCD) camera, while the angle of the light beam is recorded by the internal mechanisms of the scanner; a calculation is made between these two elements and the relative distances are determined. The accuracy of the final scan data is reliant on the accuracy of the light angle recorded (Boehler, Heinz, and Marbs 2002, 434). Errors occur within any type of laser scanning method and they become prominent in the triangulation dataset when recording edges. The errors seen within edge detection are a flat triangulation of data that are unrepresentative of the original, and occur when part of the laser point or line is partially visible on a surface edge.

Triangulation-based scanners require a number of multiple scan positions that are close to one another to avoid general issues within the field of view. The process involved includes a range map capture; conversion to point data; meshing; and removal of unwanted errors. Multiple scans provide a jigsaw effect where each of the scans is unified as one; the majority of data that are collected are redundant due to overlap. Most triangulation-based scanners work within a limited range of light and will not work if the ambient light is too dark or too bright. They will also not record black or shiny surfaces unless blue light technology is incorporated within the scanner system. Blue light technology projects a pattern across a surface where two cameras capture the displacement of changing pattern; this depth variation in the displacement of the pattern provides a calculation of the measurements. Unlike the CCD camera system, where single measurements are taken based on where the light contacts the part of the surface recorded, the blue light allows for a complete surface capture. Blue light technology follows more of a structured light processing variation but enables

micron resolution and has the ability to record dark and shiny surfaces.

Time-of-flight scanning is a technique that is based on the understanding of the speed of light. The method works by projecting a laser beam onto a surface that is returned along the same path. As the speed of light is known, the scanner calculates the time that it takes for the laser to return, creating a distance based on time. A time-of-flight scanner is usually set up to record these lengths at intervals of a picosecond through a rotating mirror, allowing several hundred thousand points to be captured in a second. The method can be used on a wide range of areas and is more suited to recording landscapes, through a 360-degree horizontal view from the ground, and in a fixed position for light detection and ranging (LiDAR) capture (see AIRBORNE LASER SCANNING AND LIDAR). The majority of scanners have the ability to record a distance of up to 300 m, with some Leica scanners having the ability to record up to 600 m. Most time-of-flight scanners allow for the resolution and the distance of the point data to be set manually within the capturing software. Photographs are also captured during this process and are projected onto the point clouds to provide red, green, and blue (RGB) values per point.

Time-of-flight laser scanners can be seen as an advanced total station (see TOTAL STATION). One main drawback to the technique is the time associated with recording one scan; this is dependent on the distance and resolution chosen, as well as the equipment used, but can take several hours to complete. Smaller distances do not equate to shorter scan times as a greater point density can be recorded. When collecting data, a consideration has to be made in terms of the level of detail required and the time available to record these scans. The majority of operators will place the scanner in a central position, record an overall scan, and then focus on specific areas at differing point spaces. Further considerations have to be made in terms of the areas recorded, especially in large public spaces. To capture longer distances, a stronger light source is required; most time-of-flight scanners utilize a class 2 or 3 laser, requiring the operator and public to be set distances away for health and safety reasons. Creating scans in public spaces also becomes problematic when the laser is interrupted by

movement, creating unwanted data and potential errors in the returning signal.

Phase laser scanning is similar to time-of-flight except that comparisons are made between outgoing and returning signals of a single laser beam rather than through the time taken for the light to return to the device. Phase laser scanning does this by modulating the power of the laser beam, where changes in distances are calculated through the differing returned frequencies (Petrie and Toth 2008, 18–19). The technique provides a greater accuracy of data due to the phase shift of the laser beam; it provides a faster data acquisition and offers a reduced amount of erroneous data. The technique works best within a limited distance range of up to 100 m. The method, as is the case with time-of-flight, allows for the collection of data in all ambient light conditions, from very dark to extremely bright environments, and includes the capture of photographs. The majority of existing phase scanners work with a limited manual control concerning distances, point spacing, and color exposure. Unlike the time-of-flight technique, the scanners cannot specify exact areas of interest and focus on a specified field of view. The systems provided by Faro are lighter and easier to work with and include a global positioning system (GPS) device, height sensor, compass, and high-dynamic range (HDR) imaging technology (see COMPUTATIONAL PHOTOGRAPHY). The phase systems currently available incorporate a class 1 laser, limiting the range of the device but making it safe for all capture scenarios. For both the time-of-flight and phase systems, targets can be used in the collection of the data to assist the stitching process. Current software packages allow for a direct cloud-to-cloud comparison, providing great control over the stitching process.

There are many issues that need to be considered when using laser scanning within archaeology: namely registration of the scans, field of view, density of data capture, and the ability to add additional information (Barber, Mills, and Bryan 2003, 620). A scanner relies on what it can see; if obstructions are present, no usable data will be collected. If the data are captured with too high a point spacing, the model will show little surface differences; if the point spacing is too small, the data may be too data intensive to use. The higher the point density, the greater the computing power needed and the greater the

file size. Within archaeological-based recordings, environmental issues are also a concern. Inadequate mounting of the device can lead to the field of view being limited and key regions missed. Nearby vibrations lead to errors in the recorded data; and temperature variations in the scanner (going from cool to hot areas) affect the operating functionality and ability. Within the recording process, errors can also be created through the capture of reflective, opaque, or uneven surfaces, where the returning laser signal is sent back via different angles or not at all. Developers have many ways of counteracting these complications, through range limits, laser class type, increased field of view, and better registration software to remove erroneous data.

There are disadvantages associated with the use of laser scanning. The first is that laser scanning, through the collection and processing of the data, takes a significant amount of time, skill, and money to complete. The time associated with producing a finished model varies, but for every day spent capturing, a week of processing is required. This can be reduced depending on the object or site that is recorded and through the correct preparation and forward thinking of how each scan will be registered. The technique is not suited to recording every type of material or surface: shiny reflective surfaces may reflect the laser; black areas absorb the laser and affect the return rate; and transparent features, such as glass, will struggle to record only the exterior surface detail.

The method is not the best tool for recording all archaeological features and should not be used instead of traditional means (see FIELD SURVEY); rather, it should be used in conjunction with them. It provides a complete replica of a given site or object and allows for a number of post-processing options to help with understanding the past. The method is time consuming, but the results provided are generally superior to other types of surface recording methods. Methods such as photogrammetry (see DIGITAL PHOTOGRAMMETRY) are comparable, but the results gained are reliant on the operator and camera system used; structured light scanning provides equally suitable data to triangulation-based scanners but relies on manually calibrated light patterns; computed tomography (see COMPUTED TOMOGRAPHY) provides internal and external details but is too

expensive for most archaeological research. The use of laser scanning within archaeology is on the rise, but its use should be dependent on the research questions asked and it should not be used simply because it is an available tool. Great skill, time, and resources are necessary to produce usable data. Without training, the production of models can be greatly hindered and errors contained within the data can affect the outcomes of the research.

Lidar Data Visualization and Processing

ŽIGA KOKALJ

Research Centre of the Slovenian Academy of Sciences and Arts, Slovenia

KRIŠTOF OŠTIR

Research Centre of the Slovenian Academy of Sciences and Arts, Slovenia; University of Ljubljana, Slovenia

Light detection and ranging (LiDAR) data processing for archaeological purposes converts raw point clouds into products that support archaeological investigation and can be more readily manipulated. The practice comprises the following tasks: automated classification of returns; manual editing and enhancement; accuracy assessment and quality control; generation of products; and visualization for feature detection and interpretation. The tasks are iterative and often overlap.

Automated classification of returns

One of the key benefits of using Aerial Laser Scanning (ALS) for archaeological exploration is the ability to strip away vegetation cover where gaps in foliage allow laser scanning to penetrate to the ground surface (see AIRBORNE LASER SCANNING AND LIDAR). A certain percentage of detected returns, depending mostly on vegetation density, will come from the ground even in woodland, thus allowing the creation of a bare-earth elevation model and observation of archaeological features in forested and scrub landscapes. To accomplish this, returns must be classified in the first stage of LiDAR data post-processing (processing steps applied to LiDAR point clouds). Classification (also referred to as filtering) assigns descriptive classes to LiDAR returns in accordance with a classification scheme (typically

bare-earth terrain points (ground), noise, vegetation, buildings, but also other anthropogenic features and objects of interest, and water). The primary task is to distinguish ground and non-ground points and this process is usually highly automated.

An essential step that can be done either before or during automatic detection of ground points is the identification and indication of noise—that is, extremely high or low points outside the range of likely elevations for the project area. The main benefit of flagging (tagging, attributing) noise points at the beginning is to gain better control over the visual representation of a point cloud, because software packages rely on statistical minimum and maximum values to color code it. Most classification algorithms are very sensitive to the influence of low noise and therefore have built-in procedures for its exclusion. However, manual identification of low noise is often required for specific applications that demand very exact representation of terrain, for example hydrology and archaeology.

Among the more important parameters that define the classification process are relief severity (flat, rolling, hilly, mountainous), vegetation cover (open, light, medium, dense vegetation), level of urbanization (individual houses, blocks, skyscrapers, warehouses), and point density. Different ground-filtering algorithms have been developed to cope with specific tasks or environments. Pfeifer and Mandlbauer (2008) describe, evaluate, and compare the currently available algorithms, and combine them in four groups:

- morphological filters, which are based on the principal presumption that the smaller the distances between a ground point and its neighboring points, the lesser the height difference accepted between them;
- progressive densification filters, which rebuild the ground by iteratively classifying more and more points as ground;
- surface-based filters, which start by initially assuming that all points belong to the ground surface and then remove those points that do not fit;

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

© 2018 John Wiley & Sons, Inc. Published 2018 by John Wiley & Sons, Inc.

DOI: 10.1002/9781119188230.saseas0347

- segmentation-based filters, which initially group points into homogeneous segments and then classify segments rather than individual points.

There are many variants and extensions within each group and some classification algorithms combine different approaches. Software developers do not usually disclose the details of the solution implemented, but may provide some basic guidelines for choosing parameters in different environments. Thus, users mostly gain knowledge and experience through trial and error. This can be frustrating because using the most appropriate algorithm with optimal settings is fundamental to producing the best possible elevation model in which archaeological topography will be represented. Archaeologists therefore have to be aware of the types of classification errors likely to be introduced by different filtering algorithms, as these may make the difference between features of interest being included in derived models or being excluded.

Aggressive settings of filtering parameters remove points that should be retained, for example, classifying small ridges or peaks as vegetation, producing type 1 errors, which are more common with data that have been processed for purposes other than archaeology. These errors can have a detrimental impact on detection of archaeological remains because small-scale topography may be classified as vegetation and will therefore not be present in the elevation model or in any of the subsequent visualizations. On the other hand, inclusion of points that should be removed, for example, retaining some vegetation or buildings points, produces type 2 errors. This results in some visible artifacts in an elevation model. With good knowledge about the behavior of the algorithm used, artifacts are quite predictable and restricted, and do not pose a big issue for interpretation.

When producing an elevation model for archaeological interpretation, the practical aim is usually to optimize the settings of filtering algorithms in such a way that vegetation is removed while the morphological characteristics of small relief features underneath it are preserved to the maximum extent. This can mean that buildings and other similar “discontinuities,” which need relatively aggressive filtering, will remain in the

resulting digital elevation model (DEM), which is not therefore strictly bare-earth terrain (see further discussion later).

Manual editing and enhancement

Because automatic classification is only accurate to a certain extent, visual inspection and manual classification are essential steps in obtaining a good result. This involves familiarity with the specific landscape, and knowledge of fundamental mapping principles, conventions, and best practice. Manual classification therefore relies heavily on the experience of the operator. Refinement of the elevation model is usually done on a point cloud which has been previously classified by an automated algorithm, reassigning points that have been categorized incorrectly. Points can be colored by intensity, classification, height (relative or absolute), or drape (single or multiple rasters), and viewed against background imagery (orthophotos, produced elevation models, thematic or topographic maps), as profile cross-sections, or in three dimensions to check for anomalies and artifacts.

Decisions on which area to inspect more carefully and which points to reclassify depend on the overall geomorphology and type and structure of the vegetation typical to the area. Special attention has to be paid to rough terrain or discontinuous slopes, dense forest areas with very few ground returns, and regions with low and dense vegetation that is often ignored by ground filters. The occurrence of different artifacts or unnaturally smooth terrain can be effectively predicted by mapping the density of laser points representing the ground and density of the vegetation canopy above them. Automated filtering will often remove valid ground points where steep berms and levees have been constructed in flat terrain, as it is unable to distinguish them from a row of vegetation. For the same reason, most filters remove narrow upstanding structures, such as walls, under a canopy and the operator might wish to reclassify these. While carrying out manual classification on a large dataset may be beyond the resources (or interests) of many archaeological projects, careful checking and correction of the classifications over areas of interest

can help in the recognition of archaeological features and is fundamental to the creation of good elevation models for visualization.

Accuracy assessment and quality control

Quality control is a compulsory step for ensuring that the acquired dataset meets the accuracy requirements and is fit for purpose of intended inquiries. Data providers have to implement routines and consistent checks to ensure data integrity, correctness, and completeness. Various public agencies and private entities have published a number of guidelines and standards for accuracy and quality reporting for LiDAR data products, which list many parameters that have to be recorded and assessed, both quantitatively and qualitatively. The most important ones that digest the data quality and that every user should be familiar with are the planimetric and vertical accuracy of acquired points, pulse density, (ground) point density, the quality of classification, possible data gaps, and lack of overlap. For archaeology, the average density of (all) points is of minor importance to the knowledge of the distribution and density of ground points and data gaps. Also important is the visual inspection for artifacts and anomalies, which not only are aesthetic but also affect the accuracy of analyses based on the terrain surface.

Generation of products

Rather than looking at the point cloud, interpreters spend most time inspecting rasterized products such as elevation models and, even more frequently, derived visualizations. The method used to produce the elevation model from the point cloud is important, because one wants good models even in places where the density of ground points is insufficient to accurately map the ground under forest at a given resolution, despite a high scanning density. In such cases, the rasterization algorithm has to “fabricate” (infer from neighboring points) the representation of the ground. The appearance of this fabricated ground varies, but the most important influence of various algorithms is on

the general smoothness and preservation (clarity) of edges. In general, the Natural Neighbors (NN) method generates a very smooth terrain, Inverse Distance Weighted (IDW) method introduces steps, rasterization with Triangulated Irregular Network (TIN) introduces triangles, and splines create a range of artifacts.

Typical rasterized products include various elevation models, such as a digital bare-earth (terrain) model (DTM) and a digital surface model (DSM), which includes vegetation and is thus useless in forested landscapes but can be superior to a DTM for detecting archaeology in meadows, and any other type of DEM—for example, containing terrain and buildings, point density calculations, and intensity of return image. Having buildings included in the elevation model is not a problem because buildings do not obstruct the view of small topography, and in many cases help improve interpretation as they offer visual clues to the age of cultural features of interest and are distinct orientation points in the landscape.

While any one of the rasterized products gives certain information about the landscape, to explore the archaeological topography thoroughly, DEMs have to be presented with specific visualization techniques.

Visualization for detection and interpretation

Some visualization techniques can only have a presentational value, while others based on specific spatial analysis (see SPATIAL ANALYSIS) can produce results that are related to physical quantities. While the latter have mainly been developed in other scientific fields and for specific purposes, they have also proven useful for making sense of detailed elevation models. Their archaeological value varies significantly with respect to the characteristics of structures observed, including size, shape, orientation, concavity or convexity, degree of prominence, and edge type. Not all methods can be recommended for interpretation when relative or absolute comparisons need to be judged. This is because most visualizations can change the observable properties of structures, depending on the settings used in the calculation. While there is no ideal visualization that would

be effective in all situations, a good visualization should meet the following criteria:

- Small-scale features must be clearly visible.
- The visualization must be intuitive and easy to interpret, that is, the users should have a clear understanding of what the visualization is showing them.
- The visualization must not depend on the orientation or shape of microrelief features.
- The visualization should work well in all terrain types.
- Calculation of the visualization should not create artificial artifacts; it can, however, highlight the existing ones.
- It must be possible to calculate the visualization from a raster elevation model (either a terrain model or as a result of dedicated processing).
- It must be possible to study the result at the entire range of values (saturation of extreme values must be minimal also in rugged terrain).
- Color or gray scale should be effective with a linear histogram stretch; manual saturation of minimum and maximum values is allowed.
- Calculation must be fast; that is, it should not slow down the interpretation process.

The assessment and evaluation of several visualization techniques has been carried out by Kokalj, Zakšek, and Oštir (2013). It is difficult to categorize them in exact groups because of their complexity, usefulness in a range of applications, various computational methods, and combinations. The following paragraphs therefore list a few of the most common methods used in archaeology, along with their main characteristics.

Analytical hill-shading is the most common technique of relief representation. It is based on direct illumination which makes it possible to intuitively recognize relief features. However, it also has several drawbacks. The most critical are its inability to represent linear objects that lie parallel to the direction of the light source and saturation of shadow areas. A number of authors have commented on its shortcomings and proposed routines to at least partially overcome these, for example with shading from multiple

directions and summarizing the results with principal component analysis (see PRINCIPAL COMPONENT ANALYSIS) (PCA). PCA removes redundancy, so there is no need to look at multiple images, but it is data dependent so does not provide consistent results with different datasets.

Methods of relief illumination include solar radiation modeling, sky illumination modeling, sky-view factor, anisotropic sky-view factor, and openness. The first two are very demanding to compute. Solar radiation models also suffer from saturation in shadows, but give information about the suitability of landscape for settlement and agriculture. The others are proxies for diffuse illumination and are very good for revealing micro-relief morphology. They do not produce saturated areas and provide clear distinction between protruding features and depressions, so they are particularly useful for observation of complex features on varied terrain. Openness is also a trend removal method and completely removes the sense of general topography. Sky-view factor, on the other hand, preserves the sense of general topography. It is a good all-purpose technique, and works especially well in combination with other methods, for instance hill-shading and slope.

The techniques of local range adjustment of height values (histogram stretch, color cast, color ranging, elevation differentiation) are best for very flat areas because linear histogram stretch retains the visual information on elevation; however, they do not work with uneven terrain. With terrain, especially if slopes are gentle and long, trend removal methods can be used to produce local relief models. The basic idea is to calculate the broader morphological features, such as hills and valleys, and remove them from the terrain data so only the small-scale features remain. Local relief models highlight small topographic differences and can be used as input to other methods. The main disadvantage is that they introduce artifacts, such as artificial banks and ditches, that can mislead the interpreter. Slope gradient presented in an inverted grayscale retains a very plastic representation of morphology and when shown together with hill-shading works well on most types of terrain. Two noteworthy techniques are also local dominance and multiscale integral invariants, which are especially suitable for detection of very subtle features.

Spatial (convolution) filters, for example those developed by Laplace, Robert, Sobel, Prewitt, and Frei and Chen, enhance high-frequency information. The main problem with using these is that along with emphasizing the features of interest they also accentuate noise in the data, but are nevertheless useful when searching for very distinct structures. Many other terrain visualization techniques exist and occasionally they are evaluated for specific use in archaeology. The described techniques not only are suitable to present LiDAR relief models, but also can be used with raster elevation models produced from any other source, for example image-based 3D modeling or structured light scanning. They can be applied to data of different spatial resolution (local, regional, continental, global), representing various entities (object, site, landscape).

Automated archaeological feature extraction

Research is now focused on automated processes that support detection and interpretation of anthropogenic relief. The whole procedure from point cloud classification to generation of various visualizations can already be highly automated; however, the processes of observation, interpretation, feature identification, and creation of archaeological information (i.e., an interpreted map) are still mostly operating in human time—that is to say, they can only proceed at the rate at which an individual can examine images, identify features, and map them (Cowley 2012). With larger (countrywide), more complex, and accurate LiDAR datasets becoming freely and openly available, the pressure is now on to develop techniques that will enable automatic detection, if not interpretation, of archaeological features. Cowley (2012) argues that visual inspection and (semi) automatic approaches should be complementary and both used in appropriate contexts, recognizing, for example, the different demands of extensive mapping where site detection is paramount or detailed understanding of a landscape where archaeological experience and knowledge are important. Continual and iterative improvement of processing algorithms has already enabled successful detection of pits and mounds, especially in a

“controlled environment,” that is, a setting with few similar modern or natural features, while automatic detection of other archaeological features of regular geometric shape, such as squares and straight lines, remains elusive precisely because of the difficulties of weeding out modern anthropogenic content. Most methods involve a form of template matching or geographic object-based analysis, and decision rules. For now, the results of automatic archaeological feature extraction therefore provide insight into a general spatial pattern rather than accounting for all individual features.

Magnetic Resonance Imaging (MRI)

HANS STODKILDE-JØRGENSEN

Aarhus Universitet, Denmark

Magnetic resonance (MR) scanning is most often understood as image acquisition of anatomic structures in patients, and this nondestructive scanning technology is a widespread clinical diagnostic modality. Magnetic resonance imaging (MRI) provides not only static anatomical images, but also dynamic recordings of functions in various organs such as the heart, the kidney, and the brain.

Magnetic resonance is based on the precessing movement of nuclei aligning to the static magnetic field of an MR scanner. The precessing frequency (Lamour frequency) is determined by the strength of the static magnet field and a so-called gyromagnetic ratio specific for the individual nuclei. The precessing frequency for ^1H in a standard 1.5 Tesla magnet system is around 63 MHz, which is very close to the commercial radio transmission frequency. Electromagnetic waves used for excitation of atoms at this frequency do not imply any ionization in tissue. Some precessing atoms align to the direction of a permanent magnet field and can be excited by the radio waves transmitted through an antenna system (coil). Through this excitation, atoms absorb energy and flip into an orientation anti-parallel to the direction of the static magnetic field now carrying a higher level of energy. When the excitation is ended, the anti-parallel-oriented nuclei will start a flip-back process and the release of absorbed energy. This can be recorded by a receiver coil system.

High pixel resolution, optimal signal-to-noise level, and recording time are always compromises in clinical scannings. However, scanning time is usually not an issue when scanning archaeological artifacts. As a result, scan data can be acquired with a pixel resolution in 3D scans well below 1 mm, and at the same time with

sufficient signal-to-noise ratios. Even though mobile scanners loaded on a heavy truck exist, most scanners are stationary installations difficult to bring to remote locations (Rühli et al. 2007). Scanner designs for many different purposes are on the market. Closed magnets come in sizes ranging from a few millimeters to more than 60 centimeters in bore diameter. Open scanners exist as well, for instance for veterinary use, and desktop magnets. A broad range of field strengths are used; but, in small-bore magnets with higher fields, image resolutions can be much better than in whole-body clinical scanners. If archaeological remains can be removed and prevented from drying out, tissue structures can be visualized as in Figure 1, which shows an MRI of part of the intestines of a more than 2,000-year-old Danish bog man (Stødkilde-Jørgensen et al. 2007). The intestinal tissue was preserved in alcohol shortly after its discovery and MR-scanned more than fifty years later. Even though only the submucosal layer of the intestinal wall is left, the image contrast is still sufficient.

The major strength of MRI is the possibility to encode the individual pixel values in the images (image weighting) with a large range of biochemical or physiological properties coupled to the concentration or movement of specific atoms. Due to the large availability of and strong echo from the hydrogen nucleus, this is most often the basis for MRI. Water and fat in the body add substantially to the total proton concentration, and thus to the MRI signal intensity. Spatial information on atom movements can be used for depicting water diffusion in the tissue, and in this way it is possible to estimate a so-called apparent diffusion coefficient dependent on the water content distribution between the interstitial space and the intracellular space. Further to this, diffusion tensor images of longitudinal tissue structures can be depicted, for instance axonal fibers in the brain or muscle fibers.

MRI in archaeological artifacts such as ancient mummies is often hampered by the usually very low amount of water present in the specimen, as the hydrogen atoms in water are the origin of the signals used for MRI. To avoid bacterial or fungal

growth, most museums keep the mummified artifacts dried out; what is more, they may have employed different conservation maneuvers, with wax or tanning. These present difficulties for applying MRI scanning that can be overcome to some extent by using MR sequences with very short echo times. These MR excitation sequences have been developed along with the ongoing technical improvement of equipment performance and compensate for the low content of moveable hydrogen atoms in dried-out soft tissue and for short transverse relaxation times in solid tissue such as bone structures. With such ultrashort echo-time excitation sequences it has been possible to visualize anatomical details in an ancient mummified hand dehydrated with natron and embalmed with resin (Ozen 2016).

In ancient Egypt artificial mummification was carried out by applying a blend of NaCl , Na_2CO_3 , NaHCO_3 , and NaP_2SO_4 (natron) directly onto the body surface. The subsequent high concentration, especially of sodium, in the artificial mummification suggests that MRI based on the ^{23}Na atom could be applied together with ^1H MRI, as done by Münnemann and colleagues

(2007). The latter measurements showed a proton signal only from structures close to the skin surface. However, the ^{23}Na MRI demonstrated enhanced sodium signals in the entire body after the natron-based mummification process.

In some cases, specific burial traditions—for example the use of encapsulated lime–soil mixtures—ensured a relatively hydrated condition (Shin et al. 2010). In mummies buried in this way in the seventeenth century, the burial method resulted in well-preserved organs that contained enough water to enable the visualization of detailed organ structures through MRI.

MRI uses so-called Fourier transformations of the signals echoed back to the receiver coil after a radio frequency excitation. These transform the analog time-domain echo signals into the frequency domain by a number of temporal and spatial preserving operations in the image reconstruction process, leading forward to the final image. In contrast to MRI, however, in the other major MR technique, called magnetic resonance spectroscopy (MRS), the processing complexity is limited. Basically, MRS is a relative concentration measure of various molecules in

the tissue. Which molecules are visible depends on the tissue type and on the atom type excited by the radio frequency excitation. In archaeology, MRS can be applied both to organic materials and to inorganic dry materials by using so-called solid-state nuclear magnetic resonance (NMR) spectroscopy. For example, in living brain tissue, ^1H spectroscopy will show the relative concentration of N-acetylaspartate, choline, creatine, and *myo*-inositol. ^{13}C in devitalized tissue will show a number of peaks related to various fat chains. In general, because of the capacity to quantify specific chemical molecules, spectroscopy allows for studies of nutritional status, authenticity, and sources in archaeological artifacts (Giovannetti et al. 2016).

The inorganic phosphate concentration in wet archaeological artifacts might be quite low, depending on the type of the preserved tissue, for example connective tissue from corpses found in wet moors. Furthermore, if the volume of available tissue is low, solid-state NMR spectroscopy is required, which differs from clinical MRS by allowing samples as small as one cubic millimeter of wet or dried tissue (or smaller) to be analyzed. Solid state also uses a number of techniques such as multinuclear cross-polarization (CP) and magic-angle spinning (MAS) to improve the signal-to-noise ratio.

In a study of tissue samples from the intestines of a 2,000-year-old Danish bog man (Stødkilde-Jørgensen et al. 2008), solid-state (CP) ^{31}P and ^{13}C magic-angle spinning multinuclear cross-polarization NMR were used and the resulting measurements were compared to those from a recent, surgically removed intestinal specimen.

The ^{31}P MAS spectra of the intestine from the bog man exhibited extremely low sensitivity when acquired without CP (i.e., through single-pulse excitation), and overnight runs acquired with 40,000 transients were necessary to achieve an acceptable signal-to-noise ratio, demonstrating a very broad spinning sideband (SSB) pattern.

The ^{31}P CP/MAS spectrum found in tissue from the recently deceased person was acquired at 9.4 T (161.9 MHz) using spinning speeds of 4 kHz (a) and 6 kHz (c) and a 5 mm rotor. Both spectra required acquisition of about 5,000 transients (~6 hours). In contrast to the ^{31}P MAS spectra from the bog man specimen, only a few hours of consecutive data sampling from

the deceased person were enough to generate an excellent signal-to-noise ratio. ^{31}P CP/MAS showed more than a twofold increase in intensity by comparison to the single-pulse ^{31}P MAS spectra without CP; furthermore, the line width of the individual SSBs was quite small by comparison to those in the ^{31}P MAS spectrum of the bog man. Computer simulations of the experimental ^{31}P CP/MAS spectra acquired with the two different spinning frequencies demonstrated that these spectra could be characterized by a single set of ^{31}P chemical shift isotropic and anisotropic (CSA) parameters ($\delta_{\text{iso}} = -0.64$ ppm, $\delta_{\sigma} = 97$ ppm, and $\eta_{\sigma} = 0.65 + 0.03$). A ^{31}P CSA of similar magnitude ($\delta_{\sigma} = 90$ ppm) and $\delta_{\text{iso}} \approx -3$ ppm also characterized the ^{31}P MAS spectrum of the spectroscopic data from the bog man.

The overall results of the MRS measurements showed that the ^{31}P constituents of the intestine of the bog man could be identified as single inorganic phosphate and showed a ^{31}P concentration that was lower by more than two orders of magnitude than the concentration in the intestine of a recently deceased person. This difference in inorganic phosphate content could very well be explained by the wet conditions under which the bog man was preserved for more than two millennia, which resulted in the chemical release of inorganic phosphate and its later removal through the aqueous environment in which the body was submerged.

Multi-View Stereo

BENJAMIN DUCKE

Deutsches Archäologisches Institut (DAI), Germany

History

The idea to use image pairs with sufficient angular separation to create the perception of depth dates back at least to the invention of stereoscopes in Victorian times. In the field of topographic surveying and map production, stereo image pairs served as the primary source of data for the extraction of elevation models from aerial photographs (using first manual and later digital methods) until the introduction of light detection and ranging (LiDAR) (see AIRBORNE LASER SCANNING AND LIDAR) technology. These traditional “two-view” (stereo) approaches find their natural extension in early limited “multi-view” methods, initially aiming at improving the robustness of stereo image processing. By the turn of the millennium, the fundamental mathematics for reconstructing three-dimensional (3D) geometries from an arbitrary number of views (*multiple* or *n-view* geometries) had been firmly established in computer vision. Recent advances in software technology, which have allowed *multi-view stereo* (MVS) technology to enter broad and general fields of application, have been driven by the general availability of high-resolution digital cameras and unprecedented computing power in consumer personal computers. However, the extension of MVS to large digital image series has also shifted the focus of interest to increasingly ambitious and computationally demanding tasks, such as reconstructing full 360-degree models of photographed objects or scenes. The ensuing challenges, of a technical and mathematical nature, are beyond the scope of the two-view approaches found in stereo photogrammetry (see DIGITAL PHOTOGRAMMETRY) and MVS has since evolved into its own subject of research and development.

Archaeology and architecture are favorable applications for the development and comparison of 3D reconstruction methods, as the often intricate motives found there pose interesting structural challenges for geometric reconstruction, and at the same time provide attractive and highly recognizable case studies. Practitioners in the domains of archaeology and heritage have been among the first to benefit from advances in MVS (recent examples include Dellepiane et al. 2013 and De Reu et al. 2013).

Technology

The term “MVS” does not denote a single, well-defined mathematical method or algorithm, but rather a family of computational solutions for the problem of extracting dense point clouds from large image series. A range of MVS implementations in end-user software exist that share the technical property of pushing even the most current computing hardware to its limits. They also share a set of goals with regard to their usefulness. Ideally, any implementation of MVS should have the following desirable properties: (1) It should produce point clouds that are as dense, homogeneous, and complete as the images allow; (2) it should be robust, so that images with varying contents, resolutions, and contrasts can be processed in one unified model; (3) it should be fast and allow the processing of large image series in reasonable time; and (4) it should provide the best possible geometric accuracy that the input images’ resolution and quality allow.

One of the earliest successful approaches to MVS is to first extract the 3D structure of multiple stereo image pairs and then fuse the individual results into a single model in a second step of point cloud construction. The first step poses a relatively well-defined problem (also known as *optical flow* in computer vision) that can be solved by computing a so-called *depth* or *range map*. This usually results in a very dense and homogeneous grid of 3D estimates for the field of vision represented by each stereo pair. The second step,

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

© 2018 John Wiley & Sons, Inc. Published 2018 by John Wiley & Sons, Inc.

DOI: 10.1002/9781119188230.saseas0398

however, is computationally demanding and can make the processing of large image series impractical on consumer-grade hardware. Fusing depth maps into one point cloud is a nontrivial process, due to the requirement of filtering out much erroneous data (noise) that result from the heterogeneous quality of 3D estimates within each depth map (see Furukawa and Hernández 2013, 63). To alleviate this problem, the resolution of the input images can be reduced and the processing off-loaded to an external high-performance computing service, as exemplified by the “Arc3D Web Service” (Nilsson et al. 2007).

Since upload bandwidth can be as severe a bottleneck as locally available processing power, performance remains a key issue for the usefulness of MVS software. Consequently, more current and efficient approaches to MVS focus on computationally efficient *photo-consistency* functions. These are designed to quickly identify image regions that are visible from multiple viewpoints and extract 3D information from them, thereby avoiding the redundant computations involved in fusing multiple two-view point clouds (see Furukawa and Hernández 2013, 17–37). In addition, the high-performance streaming processors found in current consumer-grade graphics cards are increasingly used for computing essential mathematical functions in parallel, partly eliminating the need for expensive multiprocessor hardware. This is made possible by open standards such as OpenCL (<https://www.khronos.org/opencl/>) and proprietary interfaces such as CUDA (<http://www.nvidia.com>).

The most significant technical limitations to the potential of MVS are imposed by the properties of the input imagery (Furukawa and Hernández 2013, 127–130; see also notes on practical application, below). Since any multiview approach has to start by analyzing single images for distinct structural features (edge detection, color gradients, etc.), photos showing weakly structured, homogeneous areas (such as stretches of sand) often produce incomplete or geometrically impoverished 3D models, as do very thin structures (e.g., grassy patches) and reflective regions (e.g., water surfaces). Some MVS implementations, such as CMPMVS (Jancosek and Pajdla 2011) are at least capable of compensating visually for this by fitting simple textured surfaces into the problematic areas of the model,

although this approach has little effect on the lack of geometric detail.

The overall maturity and robustness achieved by current MVS technology means that many implementations leave their academic incubation stages and are transferred into proprietary software for sale, where they essentially act as black boxes in the data-processing chain. Few details are published about these implementations, but comparative studies and benchmarks that highlight their individual strengths and weaknesses are still possible (Remondino et al. 2012).

Application

Any MVS-based 3D model can only be as good as the images on which it is based. The minimum requirement for successful MVS is a set of matched images (see also SfM (see *STRUCTURE FROM MOTION*)) with sufficient overlap. Getting good results is at least as much a matter of adjusting photographic habits on the human side, as it is one of mathematical finesse on the software side. There are certain prerequisites which, if met, tend to produce good results more predictably. The key factors are sufficient *overlap* between successive shots and *complete coverage* from all angles. Images should be taken while *moving around* the object or scene. This is a significant departure from traditional photo documentation techniques where a carefully chosen, small number of views are captured from an equally small number of fixed camera positions.

Practical experience indicates that there are few (if any) limitations regarding camera and lens technology that cannot be overcome with a well-planned photographic strategy and some degree of image preprocessing. Parameters such as image resolution and lens quality are of secondary concern to MVS, as long as the image series is large enough. Cheap compact cameras with relatively low resolution and low-quality lenses can still produce images that are *sufficient* for many purposes, while keeping processing times low. In fact, given limited computing resources, the ability to process larger image series at lower resolution may outweigh the benefits of higher resolution imagery for applications such as large site and aerial surveys. In some scenarios, even extreme wide-angle lenses can be

useful, provided that adequate lens curvature correction is applied in a pre-processing step. Video streams produced by cameras with high frame rates (at least 60 frames per second, to avoid *rolling shutter* effects) can be a good alternative to single-shot imagery, as they provide extremely high overlap between successive frames.

Given MVS's low cost of operation, an important debate revolves around whether it can replace expensive scanning hardware, most notably close-range, terrestrial laser scanners (see LASER SCANNING) for general application. Whereas laser scanning is an active, tightly controlled acquisition process with well-known properties, assessing the smallest level of detail and its geometric accuracy (colloquially referred to as "precision") achievable by MVS is nontrivial. Distance to object, photo sensor resolution (true low-noise capacity, not nominal pixel count), and the suitability of the image series for dense reconstruction (see considerations above under "Application") are all involved in determining the smallest detail distinguishable in the generated point cloud. Regarding achievable geometric accuracy and level of detail, comparative studies of benchmark datasets indicate that the differences between image-based methods and close-range laser scans are insignificant for many practical purposes (El-Hakim et al. 2008).

Image-based 3D modeling has the clear advantage when it comes to sheer flexibility. Compact and light-weight camera solutions are readily available for operation in extreme environments, underwater, airborne, and even microscopic image acquisition. The same can be said about infrared and multispectral photo sensors (e.g., Casana et al. 2014), as well as recent technologies such as high dynamic range (see COMPUTATIONAL PHOTOGRAPHY) and light field photography. If photographs can be taken, then there is a good chance that 3D models of sufficient quality can be extracted from them. More importantly, if current software fails, then there is still a chance that advances in the rapidly maturing fields of image processing and computer vision will succeed where older software failed. Advances in MVS go hand in hand with those in SfM: Improved algorithms for feature extraction, image matching, and automated camera calibration continuously improve the results of MVS-based 3D reconstruction. Thus, one of the great potentials of

MVS lies in the possibility to extract detailed 3D models from existing collections of photographs, even those that were not acquired for that purpose.

Multispectral and Hyperspectral Imaging

GEERT VERHOEVEN

Ludwig Boltzmann Institute for Archaeological
Prospection and Virtual Archaeology (LBI ArchPro),
Austria

What's in a name?

In the field of archaeology (and heritage in general), many documentation and examination methods are based on imaging techniques that characterize and depict artifacts in a nondestructive and mechanically noninvasive way. Multi- and hyperspectral imaging (together denoted spectral imaging) are two possible forms of such noninvasive imaging. Both are based on the detection of reflected or emitted optical electromagnetic radiation, the latter being defined as electromagnetic waves with wavelengths between 10 nm (0.01 μm) and 1 mm (1,000 μm). This detection can be better understood when considering that optical digital imaging usually generates a signal that is the outcome of a three-variable process:

- Electromagnetic radiation of a radiation source falls onto the object.
- This radiation is partly absorbed, transmitted, and reflected by the object. In addition to the specific chemical and physical structure of the object, this interaction and the specific ratio of the three processes is wavelength dependent. The interaction of both incoming energy and reflection creates a spectral radiance distribution that is sampled by the imager.
- The imager also has its own spectral response(s). It will detect and digitize the incoming radiance in specific spectral regions.

When observing a hot object, the imaging process is ideally governed by just two variables since

the thermal electromagnetic radiation emitted by the object itself should be the only radiation source (see THERMOGRAPHY). The principles of fluorescence imaging are similar to those of thermal imaging. In contrast to reflected (also denoted direct) imaging, fluorescence imaging uses a radiation source to excite electromagnetic radiation of a wavelength longer than the incident wavelengths (see PHOTOLUMINESCENCE OF EGYPTIAN BLUE). Subsequently, only the emitted portion of the electromagnetic radiation is recorded.

Most spectral imaging will, however, mainly rely on reflected radiation and only consider (a part of) the near-ultraviolet to short wavelength infrared range, from 315 nm to 3,000 nm. Theoretically, one could say that multispectral imaging starts as soon as data in more than one spectral band are acquired. However, the practical threshold is often four spectral channels, since three wavebands are conventionally acquired by a digital photographic camera and the human visual system (Bianco et al. 2012).

A normal color photograph can be considered a three-dimensional data cube (x, y, λ) in which the first two dimensions (x, y) are the spatial dimensions (i.e., the spatial location of every pixel). The third dimension (λ) is a spectral one. It corresponds to the same spatial position in three unique images, each of them holding the captured reflectance data in one of the three 100-nm-wide spectral bands. Given that these bands generally capture the reflected light in the blue (400 nm, 500 nm), green (500 nm, 600 nm), and red (600 nm, 700 nm) portion of the visible optical spectrum, normal photographs are often denoted RGB images. Every pixel of a common digital color photograph will, therefore, contain three digital numbers at the same location to represent the amount of radiation captured in the three broad spectral bands.

As it extends this traditional trichromatic digital camera approach, a multispectral device digitizes the reflected (and/or emitted) electro-

magnetic radiation in at least four different spectral bands. These bands also constitute a data cube, but one with an extended spectral dimension. This “extension” usually means three different things. First: a multispectral image is no longer a stack of three spatially co-registered images, but at least four or more spectral bands/images are acquired. Second: any of these spectral bands can cover a part of the invisible optical spectrum (be it near-ultraviolet (315 nm, 400 nm), near-infrared (700 nm, 1,100 nm), or short wavelength infrared (1,100 nm, 3,000 nm)). Third: the spectral bands are commonly between 20 nm and 100 nm wide. Although the spectral sensitivities can have a small spectral overlap similar to digital photographic cameras, multispectral instruments very often feature adjacent bands with a small spectral gap inbetween them (e.g., (450 nm, 500 nm), (550 nm, 600 nm) etc.).

Hyperspectral imaging extends this multispectral concept even further. The imagers feature a higher spectral resolution (often a bandwidth of about 10 nm) and capture more and (nearly) contiguous (i.e., adjacent and not overlapping) spectra (van der Meer and de Jong 2001). Although the borderline between multi- and hyperspectral imaging is rather discipline dependent, the threshold is often taken to be 10-12 spectral bands (Shrestha, Mansouri, and Hardeberg 2011). In other words: hyperspectral imaging creates a data cube of tens to hundreds of spatially co-registered two-dimensional images, each of them representing reflected electromagnetic radiant energy in a small and unique spectral waveband. Through a combination of all these single spectral values, every individual pixel of the final hyperspectral image holds the complete reflectance (or emission) spectrum (also denoted the spectral signature) of the object that was sampled at that specific location. Due to this characteristic, hyperspectral imaging is also known as imaging spectroscopy, spectroscopy being the study of the interaction between matter and radiant energy. Recording this spectral signature (and correcting it for the influence of the radiation source) opens up a whole world of unique possibilities for the benefit of heritage.

Applications

From here onward, no further strict distinction will be made between multi- and hyperspectral imaging and the process of capturing, processing, displaying, and interpreting images with a high number of spectral channels will just be referred to as spectral imaging. One just has to remember that the number of spectral bands, their bandwidth, and their spectral overlap can vary.

Archaeologists have used spectral imaging for various reasons, one of them being archaeological prospection. Buried archaeological residues often change the chemical and physical properties of the local soil matrix, and might be revealed by differences in the color or height of vegetation on top of the remains (i.e., crop or vegetation marks) or distinct tonal differences in the ploughed soil (soil marks). Traditionally, detection and documentation of these residues is carried out using conventional photographic methods (see AERIAL PHOTOGRAPHY). However, because spectral images allow for a more detailed assessment of specific and subtle vegetation characteristics (e.g., the red edge response in stressed versus healthy plants) and soil properties (e.g., mineral composition), they can provide more information about subsurface remains, which helps in the efficient detection, mapping, and management of buried heritage. Although numerous spaceborne spectral imaging systems are in existence (see SATELLITE HYPERSPECTRAL AND MULTISPECTRAL IMAGING), airborne multi- and hyperspectral sensors have proven to be more effective means for the discovery and detailed recording of site-level features due to their higher spatial resolution.

However, most heritage-related imaging applications are terrestrial in nature, mainly aimed at documenting or investigating artifacts or excavation profiles. One of the main reasons to use spectral imaging is due to the fact that three-band digital cameras can be considered inaccurate color reproduction instruments since their spectral bands differ from the spectral responses of the human eye. To overcome this, spectral data in more wavebands need to be acquired. In imaging applications where color accuracy is key, spectral images can vary from

four to five broad image channels up to 40 narrow spectral bands. Obviously, more and smaller spectral channels have the potential to digitize the spectral signature better, although mathematical techniques exist to approximate the spectral signature out of only a few spectral bands. Since the 1990s, there have been many studies to determine the amount of (theoretical and real) filters needed for accurate color imaging. Despite the lack of agreement on the minimum amount of spectral bands to achieve this and the related variety in processing steps (e.g., getting rid of the illumination influence), spectral imaging nevertheless enables the storage of color-accurate master copies in cultural archives and digital museums.

Given the possibility to directly assess the spectral signature of objects irrespective of their illumination, this per-pixel spectral information can be used to render the artifact for any given observer or viewing condition. The field of painting conservation exploits this characteristic to simulate how the colors of a painting were perceived under different illuminants such as candlelight and daylight. Because any observer- or illumination-specific rendering should be discounted for a reliable assessment of an artifact, spectral images also constitute essential information for research on monitoring and restoring heritage objects, predicting their appearance after cleaning and assessing possible damage by transportation.

Spectral imaging also makes it possible to distinguish the materials comprising the various objects in the scene. By comparing the spectral response of a region against the spectral response of known features (e.g., pigments and binders), it becomes possible to identify an artist's materials. For instance, this approach could be used to map the dissimilar spatial distribution of yellow ochre and lead-tin yellow pigment at the surface of a polychrome artwork. Thanks to the dissimilar spectral reflectance features of inks, spectral imaging is often used to enhance the reading of old documents. Faded fragments of writing on leather, papyrus, pottery sherds, and clay tablets can frequently be visualized when imaged in the nonvisible ultraviolet and infrared wavebands.

Drawbacks and future research

The drawbacks of spectral imaging revolve around the quantity of data that are gathered. In addition, the acquisition of data in small spectral bands makes the imaging process more noise prone compared to broadband photography. Whereas capturing, processing, and reproduction of standard photographic data can rely on a wide variety of industry-standardized tools, spectral imaging often relies on less widespread and even bespoke infrastructures. That said, a number of hardware configurations can be used to acquire spectral images. In its simplest form, a standard (or modified) digital camera can be equipped with various filters that isolate individual spectral bands. However, most systems are bulkier prototypes developed for individual research purposes, while some very complex systems (certainly in the case of airborne imaging) are produced commercially.

To view and pre- and post-process the huge amounts of spectral imaging data, dedicated software packages are needed as well. As previously mentioned, deriving the actual spectral data from the acquired output requires a major amount of signal processing and differs according to the specific hardware setup. Moreover, dedicated software might be used to mosaic the individual images (e.g., when large objects have to be imaged) or for post-processing operations such as distinguishing pixels based on their spectral characteristics.

In 2016, most spectral imaging systems were still passive (i.e., they record reflected or emitted radiation). However, laser scanning technology could change this situation in the coming decade. Although the majority of airborne or terrestrial laser scanners still operate at one specific wavelength, multi-wavelength laser setups have been in operation since 2010. Their application will certainly be a future hot research topic in the ongoing story of heritage spectral imaging, as the active emission of radiation from laser scanners makes this approach independent of any external illumination.

Multispectral and Hyperspectral Imaging of Artworks

PAOLA RICCIARDI
Fitzwilliam Museum, UK

JOHN K. DELANEY
National Gallery of Art, USA

Multi- and hyperspectral imaging consists of the capture of a number of images of the same object in a series of different spectral bands. Multispectral imaging (MSI) is the collection of a few to tens of images in narrow or wide spectral bands which may not be contiguous. Hyperspectral imaging (HSI) is the collection of hundreds of contiguous and narrow spectral band images. Once the images are assembled in a so-called image-cube and radiometrically calibrated—either in an absolute way (spectral radiance) or in a relative sense, so-called band-to-band—they provide spectral information across the entire imaged surface. Therefore, MSI and HSI are often collectively referred to as “imaging spectroscopy” or “spectral imaging.”

HSI cameras have spectral range and spectral resolution similar to bench-top non-imaging spectrometers. For this reason, imaging spectroscopy has become largely synonymous with HSI since the focus is on acquiring spectral content—reflectance spectra or fluorescence spectra—across the surface of an object. MSI can also provide useful spectral information about objects made up of few materials that can be distinguished using a small number of spectral bands. HSI is designed for the more general cases where the materials are unknown or have highly varied spectra.

The primary benefit of imaging spectroscopy is that it allows the rapid collection of bench-quality spectra across a large area. Such large datasets are

organized as 3D data-cubes where the 2D images acquired in each spectral band are “stacked” according to central wavelength or wavenumber. Thus one can retrieve the spectral information for any pixel in the imaged scene and compare it to spectral databases or to spectral data from other pixels in the scene.

Imaging spectroscopy has proven most useful in separating areas of the imaged scene into clusters of materials having the same spectral features. Such features can be used to identify materials directly, or at least to define areas to be further studied with more sensitive analytical methods for materials identification, such as Raman or Fourier transform infrared (FTIR) spectroscopy. The classification of the spectral data can be done either manually or automatically.

The spectral range over which MSI and HSI are performed depends on the materials one is interested in spatially separating (classifying), and ideally identify from the spectral features collected. The most used spectral regions are the visible (400–700) and near-infrared (NIR) (700 to ~2,500 nm). These ranges provide rich information associated with electronic transitions that give rise to color, as well as combination and overtone vibrational features—in the NIR—which often provide unique material identification. They also allow penetration of the outer paint layers, providing information about subsurface layers. While the mid-IR range (3–11 μm) offers rich vibrational spectral features, it requires more complex and costly instrumentation. Additional drawbacks include spectral distortions due to reflectance-mode spectroscopy, limitations in the depth of penetration, and the need for a thermal source.

Imaging spectroscopy (as HSI) was first developed in the mid-1980s for remote sensing of the Earth's surface (see SATELLITE HYPERSPECTRAL AND MULTISPECTRAL IMAGING); in subsequent years its application was extended to numerous other fields of research such as environmental monitoring and quality control of food and other natural products.

Since the beginning of this century, imaging spectroscopy has been increasingly used to study artworks, especially low-relief polychrome objects such as easel and wall paintings, as well as works on paper and parchment (Cucci, Delaney, and Picollo 2016; Liang 2012). These have included mostly small-scale objects measuring from a few centimeters across to approximately 2 m²; spatial sampling typically ranges from 100 μ m to a few millimeters.

The reasons why imaging spectroscopy is used to study works of art mirror those showing why this method has been successful in other fields of research: making material maps, in this case maps of artists' materials, including pigments and paint binders, fibers in historic textiles, and different types of plastics, finding non-original materials and retouched areas, monitoring degradation, and assessing cleaning and restoration treatments. A slightly more unusual application regards the visualization of information which is hidden underneath the paint layers, such as preparatory sketches ("underdrawing") as well as *pentimenti*, that is, compositional changes made by an artist between the drawing and the painting stage, often unnoticeable with the naked eye. Examples of each of these applications are briefly presented in this entry.

Spectral imaging systems suited for the analysis of artworks usually consist of the following essential components: (1) suitable lighting both in terms of spectral range covered and of acceptable light levels for the work of art; (2) an imaging objective, typically well corrected over the spectral range of interest; (3) a single-element detector or 2D detector array with good sensitivity in the spectral range of interest; (4) a dispersive spectral element, that is, a means of wavelength selection; and (5) a radiometric calibration source or reference target.

These essential components can be combined in a variety of ways to assemble a useful spectral imaging camera system. Choices to be made include where to make the wavelength selection—that is, on the illumination light path or after the imaging lens—and what type of dispersive element to use. Spectral interference filters offer one of the simplest multispectral systems that allows tailoring the spectral range each time for the particular question at hand. Imaging spectrometers offer the largest spectral resolution and

number of spectral bands, but require a longer acquisition time as they typically have much narrower spectral bands. The most time-efficient systems are imaging spectrometers that provide spatially resolved spectral information along the slit of the spectrometer.

The instrument's design usually depends on the specific goals to be achieved. For example, a researcher seeking to separate a limited set of pigments on a large or highly detailed work of art might utilize a system with a series of interference filters and a high spatial resolution camera. Investigators studying artworks with a large range of unknown pigments would find a camera having lower spatial resolution but broader spectral range and higher spectral resolution the most useful. In this case, a scanning imaging spectrometer able to capture hundreds of spectral bands at once would be ideal.

The MSI and HSI protocols used to study artworks consist of several steps, which can be broadly classified as image acquisition, calibration, and processing. A key step during post-processing of image-cubes, which is often overlooked but has an effect on the choice of imaging setup, is the need for some sort of spatial registration for interference filter systems, or even for systems using spectrally filtered lights with lenses without adequate color or chromatic aberration correction. Imaging spectrometers do not suffer from spatial registration issues, but care needs to be taken to ensure light levels are acceptable for the work of art under study.

Recent notable applications of imaging spectroscopy to the study of artworks include the identification and mapping of pigments in Pablo Picasso's *Peonies* (Delaney et al. 2016a). HSI in both reflectance and luminescence mode was used to reveal a wide range of pigments comprising vermilion, cadmium yellow, cobalt blue, Prussian blue, and an organic red colorant. The additional presence of emerald green and zinc white was confirmed by further analysis by X-ray fluorescence (XRF) spectroscopy and fiber-optic reflectance spectroscopy (FORS). As a matter of fact, spectral imaging is often used in combination with site-specific spectroscopic methods to provide more secure identification of artists' materials. Considered alone, the reflectance and/or luminescence properties of pigments

and binders in the visible and NIR range, while sufficient to separate them, do not always allow their secure identification.

Mapping paint binders is especially challenging due to their subtle spectral features in the NIR, which shift and decrease in intensity with aging. Using an exceptionally sensitive NIR imaging spectrometer, Ricciardi et al. (2012) were nonetheless able to map the selective use of a lipid-containing binder (likely egg yolk) in a fifteenth-century illuminated manuscript fragment.

A similarly sensitive instrument was used to identify sections of two sixteenth-century tapestries woven with silk and wool fibers, respectively (Delaney et al. 2016b). In both cases, the study revealed a correlation between the colorants (identified by FORS) and the fibers used in each area. In the red areas of one of the tapestries, for example, wool fibers were dyed with a plant-derived dye (madder), while silk fibers were dyed with an insect-derived dye (Old World cochineal).

Modern materials found in twentieth-century museum objects can also be analyzed using MSI and HSI. Cséfalvayová, Strlič, and Karjalainen (2011) demonstrated the potential of NIR imaging spectroscopy for the quick assessment of large collections of such works of art by building an extensive database of reference objects and spectra and using it to distinguish between different types of historic plastics.

NIR imaging spectroscopy can also be used to improve upon “classic” broadband infrared reflectography. For example, the multiple compositions known to exist beneath the surface of Pablo Picasso’s *The Tragedy* were most clearly revealed by selecting spectral bands offering the maximum contrast for each. Images collected at approximately 1,200, 1,350, and 1,500 nm, respectively, allowed optimal visualization of underdrawing for the final composition, a dying horse present in an earlier sketch for a different painting, and a series of caricatures drawn directly on the wood panel (Delaney et al. 2016a).

As imaging spectroscopy rapidly becomes an indispensable tool for conservators and heritage scientists, its combination with other chemical imaging methods continues to enhance the information it can provide. For example, visible and NIR HSI (400–1,680 nm) used with macro-XRF

scanning provided robust identification and mapping of pigments and binding media, as well as the visualization of a preparatory design, in a painting by the Italian Renaissance artist Cosimo Tura (Dooley et al. 2014). A recent review of hyperspectral methods that can be used to image artworks at a macroscopic level describes exciting developments in the use of macro-XRF and macro-XRD scanning, computed X-ray laminography, mid-IR hyperspectral imaging, and optical coherent tomography in NIR (Legrand et al. 2014).

Optical Microscopy

ELIN FIGUEIREDO

Universidade NOVA de Lisboa, Portugal

Optical microscopy (OM) is often also called light microscopy, as it is based on a focused beam of light for the examination of samples through a system of lenses. It is one of the earliest and still most commonly used examination techniques for scientific investigation, and is frequently used in the research of archaeological materials.

OM has numerous applications. Most important is the determination of the constituents and microstructure of materials. These can be different phases in metal alloys, different minerals in petrographic samples (see PETROGRAPHY AND CERAMICS), different pigments and layers in painting works (see GLAZES, SLIPS, AND PAINTS), or cells in biological samples (see USE OF BIOLOGICAL COLLECTIONS). Such observations are of practical importance since the structure and constitution of a material has implications for its physical and chemical behavior, and its conservation (see CONSERVATION), and can inform about the nature and origin of materials, as well as about materials and manufacturing techniques that were in use in the past.

Frequently, examination by OM precedes other analytical techniques such as X-ray fluorescence (XRF) (see X-RAY FLUORESCENCE SPECTROMETRY (XRF)), X-ray diffraction (XRD) (see XRD AND MATERIALS ANALYSIS), scanning electron microscopy (SEM) (see SCANNING ELECTRON MICROSCOPY), Raman spectroscopy (see RAMAN SPECTROSCOPY), or Fourier transform infrared (FTIR) spectrometry (see INFRARED ABSORPTION SPECTROSCOPY (IR, FTIR, DRIFT, ATR)), since it allows a broad and preliminary knowledge of the structure and nature of materials in a relatively inexpensive way.

There is an endless array of optical microscopes with different options and configurations available for investigation. Each one has specific advantages for different types of materials.

Equipment

Microscopes can be designed for illumination with incident (reflected) light or transmitted light. The former are commonly called metallurgical microscopes since they are used for observation of metals or ores (see ORE AND SMELTING SLAG) which are opaque. The latter are usually used in mineralogical and biological studies, since samples can be transparent to translucent. A dual-purpose microscope is capable of viewing samples in reflected as well as in transmitted light.

Based on the structure design, there are two basic types of microscopes: the upright microscope and the inverted microscope (e.g., see Figure 1). The difference relies on the orientation of the face of the polished (prepared) specimen that is being examined.

Essentially, the constitution of a microscope can be abbreviated to a light source, a condenser system, light filters, objective lens, eyepieces, and a stage. A digital recording camera is frequently attached, to allow images to be captured and treated digitally.

Various light sources are available, such as LED, halogen, xenon, Hg, and tungsten lamps. Differences can be in the intensity of the light, the quality of the continuum visual spectrum, and the possibility of obtaining monochromatic radiation.

The condenser system is an adjustable lens placed in front of the illumination system. It serves to source the illumination to a desired optical path, being capable of modeling the light trajectory and intensity by field and aperture diaphragms.

The use of filters is often required to modify the incident light and allow optimum examination of the specimen. Filters can reduce the intensity of incident light across the entire visible spectrum or they can act as selective filters, by absorbing certain wavelengths (colors). They can also act by polarizing the light, allowing the transmission of light that only vibrates in one direction.

The objective lens is the essential component of the microscope which forms the primary image

Figure 1 An inverted (motorized) metallurgical optical microscope (DMI5000M, Leica) suitable for reflected light observations. The large stage allows large samples or artifacts to be examined. A polarizing filter is placed next to the microscope.

of the examined specimen. It collects the reflected or transmitted light and combines it to form the image. The quality of the lens is thus of major importance for the quality of the final image. Many types of lens defects affect the sharpness of the image obtained, for example astigmatism, and chromatic and spherical aberrations. Various objective lenses exist on the market that correct some of these defects. Apochromatic lenses correct more chromatic aberrations than achromatic lenses, but are more expensive. A compromise is the semi-apochromatic (or fluorite) objectives, which can be found in many microscopes. Flat-field corrected objectives, called plan objectives, and are especially suited for the use of charge-coupled device (CCD) cameras. Lenses can be designed to be used with air or oil as the medium between the sample and the objective front lens. The latter provide a better image, but require more care in operation and are thus not so commonly used.

In a microscope, four to six objectives are usually mounted on a rotating nose-piece turret. Each objective has a specific magnification number (typically 5 $\times$, 10 $\times$, 20 $\times$, 50 $\times$, 100 $\times$) and

a different working distance. Thus, when switching from a low-power objective to a high-power objective it is necessary to finely refocus the image by adjusting the height of the stage where the specimen is placed. As a rule, as the magnifying power of the objective increases, the working distance decreases, resulting in the sample being closer to the front surface of the objective lens.

Each objective has a numerical aperture (NA) which is a measure of the light collection capability. The NA is given by the sine of half of the aperture angle of the objective and takes into account the refractive index of the medium between the objective front lens and the sample. Its value affects the ability to resolve fine specimen details. The depth of field in OM is typically very limited, and can only be slightly improved by reducing the NA of the system: by closing down the aperture diaphragm and/or using a lower NA objective.

The eyepiece (ocular) allows the user's eye to obtain full resolution of the objective by further magnifying the image produced by the objective. Usually, eyepiece magnification is 10 $\times$. The total magnification of the produced image is thus the product of the magnification of the objectives and the eyepiece.

The mechanical stage of the microscope is where the sample is placed and focused on. Stages allow movement in x, y, and z axes. In mineralogy and petrography, circular stages are frequently used to also allow measurements of the angle of rotation, important for polarized-light work.

Methods and uses

Since the beginning of this century, partly because of rapid improvements in hardware and software, a large variety of microscopy and imaging (see *IMAGING*) solutions have become available. Microscopes with motorized components connected to a computer with specific software can take advantage of multistep routines for the development of further visualization modes. One example is the confocal fluorescence microscopy which uses a pinhole to eliminate out-of-focus signal and is capable of reconstructing 3D (tomographic) models (see *COMPUTED TOMOGRAPHY*) of translucent biological samples. Another is the multifocus imaging technique, which considerably extends depth of field of an OM image by overlapping focused portions of successive images taken along the z-axis. The latest technique allows the examination of non-planar surfaces, avoiding conventional sample taking and preparation (of some interest in the study of cultural materials (Figueiredo et al. 2013)), and allows for the study of topographic features by applying 3D surface modeling tools (e.g., Image J software (Rasband 2018)).

In OM, besides primary brightfield illumination, a wide range of illumination options can be used for enhancing contrast. These include darkfield illumination, polarized light, phase contrast illumination, interface techniques, and various filters.

Darkfield illumination (obtained by allowing only oblique rays of large angles to strike the specimen) produces an intensity contrast image accentuating surface irregularities, such as grain boundaries, cracks, and pits. Polarized light (obtained by applying a polarized filter) is very useful for the observation of constituents by their characteristic (polarized) colors, and allows the use of crossed polars mode for the identification of anisotropic crystals. In crossed polars mode, a substage polarized filter (polarizer) and an

above-stage polarized filter (analyzer) are aligned at right angles to each other.

Since certain materials emit radiation of their own when illuminated by ultraviolet or other specific wavelength, the use of monochromatic light can be useful for the identification and structural examination of materials. Microscopes that allow such observations are frequently called fluorescence microscopes, and are commonly used in biological-based materials.

For OM observation a sample should typically have a plain polished surface, as free as possible of pits, scratches, and fractures. This is achieved by grounding and polishing the surface with progressive use of finer and finer abrasives. To allow the handling of the sample it can be mounted in epoxy resin; the mounting also facilitates future sample storage. In some cases, chemical etching (by the application of a suitable etching solution to the polished surface of the sample, normally by immersion) can be performed to reveal the structure. Examples are to detect coring/zoning, twinning, grain boundaries, and for enhancing phases in both metal and mineral samples. In biological samples, etching can also be performed; thin sections of wood can be etched and examined for identification of cell anatomy, enabling the identification of species (Schoch et al. 2007). Additionally, some organic materials can be stained with certain dyes (fluorochromes) to produce fluorescence.

When studying multilayered structures or textured polycrystalline materials, the location of sampling and sample orientation (see *SAMPLING THEORY*) are of major importance to obtain meaningful data. In the case of paintings (e.g., murals, rock art, and paintings on ceramics), sampling should ideally include all the painting layer(s) and the ground material. Observation of the cross-section will allow the study of thickness and number of painting layers, and the size and shape of pigments, and evaluate adhesion to the ground material, providing information on materials used and technical skills in ancient societies.

Studies on ceramics or petrographic samples are frequently made in thin sections (ca. 0.03 mm thick), using transmitted light due to the presence of transparent to translucent minerals. However, if opaque constituents are present, reflected light can also be used. In both cases, the use of polarized light for mineral and ore identification

is desirable (since transmitted light produces superior contrast-enhancing polarizing images, it is preferably used rather than reflected light). For example, hematite and cuprite can be seen as gray when viewed in reflected brightfield illumination or as deep red in polarized light (due to internal reflections), but hematite shows very distinct gray-blue and gray-yellow colors on twin boundaries in crossed polars (Ineson 1989). During OM examinations, the identification of temperature-sensitive minerals can provide information on firing temperatures of ceramics, and the identification of particular minerals or textures can indicate the provenance of the raw materials.

The study of archaeological metals can benefit greatly from OM examinations (see METALLOGRAPHY). Reflected brightfield illumination and polarized light allows the distinction among different phases, and also an evaluation of corrosion (see DETERIORATION). If metal phases are clearly identified it is possible to estimate the alloy composition by image analysis. The size and morphology of grains allows inference on the cooling rate of the metal, as well as reconstruction of thermomechanical processes to which the object was subjected during shaping. By etching samples with face-centered cubic (FCC) structures (e.g., copper, lead, and silver), twinning grains can be evidenced, which indicates plastic deformation prior to an annealing (thermal) treatment. Finally, the metallographic information can provide important data about the development of metallurgical skills at different periods and in different regions.

Paleoenvironmental Reconstruction

MARIEKA BROUWER BURG
University of New Hampshire, USA

While analyses of the tangible remains of human behavior are critical to the exploration of past societies, it is also of paramount importance to understand the environment(s) and landscape(s) people dwelt within. Paleoenvironmental reconstruction describes a range of multidisciplinary approaches involving varying methodologies, data types, datasets (groupings of observations based on a goal or target, with clear measurement parameters, and organized in terms of a specific problem), and theoretical positions. This research focuses on three key elements: the physical, biological, and social environments in which people existed; the ecological relationships between humans and their environment at a particular place and time; and the evolution of linked physical, biological, and social systems over varying durations of time and scales of space. The goal of much paleoenvironmental reconstruction is to approximate past human habitats (typical environments or territories, sometimes referred to as a “target environment”) to understand the potentials and limitations encountered during a human lifespan (Dincauze 2000, 7, 20–23). This research also facilitates exploration of the human role within a larger milieu (i.e., the human niche; see Evans and O'Connor 1999, 27), and the ways in which human systems navigated and negotiated instability or dynamic change in their surroundings.

Paleoenvironmental reconstruction is practiced largely by environmental archaeologists, but often requires input from a wider range of subfields (e.g., zooarchaeology (see ZOOARCHAEOLOGY), geoarchaeology (see GEOARCHAEOLOGY), paleoethnobotany (see PALEOETHNOBOTANY), archaeometry (see ARCHAEOMETRY), bioarchaeology (see BIOARCHAEOLOGY)) and disciplines

(e.g., palynology (see PALYNOLOGY), botany, biology, ecology, geomorphology, pedology, geology, climatology, oceanography). Initial interest in paleoenvironmental reconstruction for archaeological investigation can be traced to northern and central European (especially Scandinavian) archaeologists in the nineteenth and early twentieth centuries. Pioneering archaeologist Jens Worsaae collaborated with biologists and geologists to develop paleoenvironmental settings within which he believed archaeological remains should be situated (Trigger 1989, 80–82). Graham Clark's research at the site of Star Carr, UK, built inferences of Mesolithic hunter-gatherer economic and social behavior upon reconstructions of the post-glacial landscape using waterlogged deposits and evidence from faunal, vegetal, and mineral remains (Clark 1954). In the United States, Julian Steward's multilineal, cultural ecology approach focused closely on environment as a driver of human behavior and change, and catalyzed important environmentally underpinned research in the 1960s and 1970s by scholars such as Karl Butzer, Kent Flannery, and many others. Such environmentally driven research precipitated the archaeological specializations of zooarchaeology, archaeobotany, and geoarchaeology (among others), specializations that are widespread today. Formation of the Association for Environmental Archaeology (AEA) in 1979 formalized this arena of study, as did the success of the AEA's peer-reviewed journal *Environmental Archaeology*, now in its twentieth year of publication.

The strength of this multidisciplinary approach—primarily that it integrates the methodological and analytical strengths of well-developed and theorized fields to obtain robust reconstructions—is accompanied by some inherent limitations. It is often difficult to integrate the theory, research goals, and methodologies of specialists from diverse fields. Projects involving many scientists must be conscious of the increased potential for inferential and explanatory mismatch, and of the uncertainty and error generated by incompatible frames of

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

DOI: 10.1002/9781119188230.saseas0432

reference and data incorporation. Reconstructions that successfully incorporate a diverse array of complementary data types (those configured at congruent temporal scales and derived from similar geographical locations) benefit enormously in robusticity (increased confidence that the reconstruction is accurately modeling the target environment in the past). Dataset consistency is also crucial, as all datasets should support a similar reconstruction scenario; mismatch between datasets is an indicator that one or all of the sets must be further evaluated. Strong paleoenvironmental reconstructions must strike a balance between the type, quantity, and quality of data incorporated into useful and compatible datasets (Dincauze 2000, 24–26).

Another inherent issue in paleoenvironmental reconstruction relates to inductive barriers imposed on researchers. While the primary goal of this research is to achieve the most probable representation of a target environment, it must be acknowledged that even the most detailed reconstructions are nothing more than multiple working hypotheses that generate a model, simulacrum, or best guess about past human habitats, and are supported by the most appropriate and current data available. However, researchers can never be certain how close they are to approximating the target system. Further, much paleoenvironmental research incorporates considerable amounts of proxy data, quantitative and qualitative values that indirectly inform researchers about past environmental conditions that have not been preserved or cannot be directly observed through currently observable data. Researchers must be vigilant when using proxy data, as too much reliance may lead to a false sense of reality and even tautological reasoning. Advances in archaeological taphonomy (see TAPHONOMY) have helped to alleviate some of these inferential issues, strengthening understandings of the impact of past natural, physical, and biological processes on the archaeological record. However, the issue of equifinality (different causal factors and processes leading to a similar observable end state) must be addressed, in addition to the acknowledgment that past environments are comprised of myriad agents and forces linked in a multitude of complex relationships, and that straightforward analogy cannot necessarily be assumed (Williams and Jackson 2007).

Paleoenvironmental reconstructions undertaken for archaeological purposes vary greatly in spatial scale, scope of environmental variables, and temporality. Each reconstruction is therefore unique in its construction and intended product. As available and accessible data will affect the end result most greatly, data from all four Earth spheres should ideally be included (atmosphere, hydrosphere, lithosphere, and biosphere). However, data from these spheres differ in type and longevity, and require very different collection strategies, analytical procedures, and theoretical frameworks.

Many paleoenvironmental reconstructions begin with a strong foundational understanding of the abiotic circumstances of the physical landscape. This is a difficult step, given that landscapes are dynamic entities. Geomorphology, geology, and sedimentology provide the primary sources of evidence. Coring (see CORING), augering (see AUGERING), remote sensing (see AIRBORNE REMOTE SENSING), electrical resistivity (see ELECTRICAL RESISTIVITY), magnetometry (see MAGNETOMETRY), and ground-penetrating radar (see GROUND-PENETRATING RADAR) are key methodological tools that facilitate investigation of the terrestrial and marine subsurface. Such research provides direct evidence about the evolution of landscape features and should be underpinned by sound sampling strategies (see sampling theory (see SAMPLING THEORY), sampling in geoarchaeology, and geomorphological survey (see GEOMORPHOLOGICAL SURVEY)). Knowledge of sediments, soils, sedimentation rates and processes, and soil development are important, as is the inclusion of information about broader geological processes such as glaciations (and associated forces of isostasy), geophysical events (earthquakes, tremors, volcanic eruptions), and oceanic changes (eustatic and global sea-level change). Modern computer applications such as geographic information systems (GIS) have facilitated the harnessing of such wide-ranging datasets. Maintaining complementarity, consistency, and scalar congruence among and between these datasets is of critical importance during the design and development of any paleoenvironmental reconstruction. To obtain detailed diachronic models of past physical landscapes that can be used to investigate human questions and processes, archaeological modelers

must allocate additional effort toward correlating geophysical and geological data with the human spatiotemporal scale, which is generally narrower in spatial extent and contracted in time.

Subsequent to the generation of sufficiently detailed physical landscape reconstructions, the next procedural step generally involves superimposing and integrating biota, including vegetation, fauna, and, of course, *Homo sapiens*. There are many sources of direct evidence from which information about such environmental components can be drawn, and methods and techniques from various biological subdisciplines are often incorporated. Palynology, the study of pollen grains and spores, is analytically well developed and can yield far-reaching inferences about plant distributions and successions, not to mention proxy evidence about environmental modifications (natural or cultural). Botanical microfossil (phytolith analysis (see PHYTOLITH ANALYSIS) and starch granule analysis (see STARCH GRANULE ANALYSIS)) and macrofossil research is also developing a robust methodological practice, and should add complementary evidence to palynological results (see Pearsall 2015, and others). These archives of natural data, in addition to tree-ring and isotopic analysis, can provide information about climate and climate change in the ancient atmosphere, the ongoing dynamics between the lithosphere and hydrosphere, and the timing, tempo, and cadence of such changes. For example, biotic data such as the initiation of peat growth, present in geomorphologic cores of the subsurface, indicate changes in both the lithosphere and hydrosphere (sea-level rise and inundation of previously above-water landform features), as well as global atmospheric changes in solar radiation, trace elements, wind patterns, and precipitation and moisture levels.

Direct evidence from vegetative sources have proven to be incredibly instructive for understanding faunal distributions, habitats, and territories, migrations, and speciation and extinction events. Inferences are greatly strengthened when complementary direct evidence can be obtained from the animal micro- and macrofossil record (diatom and foraminifera analysis (see DIATOMS), land and freshwater molluscs (see LAND AND FRESHWATER MOLLUSCS), marine molluscs (see MARINE MOLLUSCS),

ostracods and cladocerans (see OSTRACODS AND CLADOCERANS), and insects (see ARCHAEOENTOMOLOGY)). The importance of biotic data in paleoenvironmental reconstruction undertaken for archaeological purposes lies in its congruency with the human spatiotemporal scale (most plants and animals share a similar scale of existence to humans). More problematic are the issues of consistency between various direct and indirect lines of biotic information, and the question of how many such biotic datasets to incorporate into a reconstruction to achieve maximum complementarity and diversity without bogging down the tools used to synthesize the information (i.e., the geospatial software and computer hardware). Furthermore, no paleoenvironmental reconstruction is complete until our own species, *H sapiens*, or our ancestors, have been added to the mix. Human actions are typically considered as part of biospheric processes, although some argue the Earth has entered an entirely new epoch (the Anthropocene) with a new and growing Earth sphere (the Anthrosphere), in which the impact of one biological species is increasingly impacting the conditions of the other integrated spheres (e.g., in creating climate change that leads to glacial retraction, rising sea levels, and changes in the geophysical landscape and biotic communities at a worldwide scale) (Crutzen 2002). The primary source of data about the human component of the environmental system derives from archaeological data.

Throughout this process, consideration of climate and climate change should be made, as the conditions of the atmosphere impacted the physical landscape and biotic communities in both the short and long term. While much can be learned by proxy about the past climate from the physical landscape (presence of landform features and analysis of pedogenesis and diagenesis) as well as biotic data (data derived from studies of dendrochronology, palynology, diatoms, phytoliths, and macrofossils), it is helpful to reference data from other sources. For example, ocean sediment and ice cores can yield valuable information (in the form of benthic fossils and elemental ratios of inorganic sediments) about temperature swings, changes in the moisture content of air masses, and the patterning of winds and storms. Periodic consideration of climate for a given place in time, and investigation of the dynamics

of climate change, is critical for building a robust paleoenvironmental reconstruction. One recent research initiative that built such reconstructions is the Interdisciplinary Archaeological Research Program carried out at the Maasvlakte 2 Harbor in the port of Rotterdam, the Netherlands (Moree and Sier 2015). The resulting paleoenvironmental scenarios revealed ecologically dynamic, resource-rich river dune complexes that were utilized by Mesolithic hunter-gatherer-fishers for thousands of years.

Paleoenvironmental reconstruction has primarily been used as a methodological tool within the archaeological science toolkit, to “set the stage” for deeper probing of the human condition, ostensibly the more interesting and rewarding end goal. Today, however, advances in data collection and computer technologies are permitting researchers to heuristically investigate broader questions about nonlinear human behaviors, decision-making, and cultural processes through their paleoenvironmental reconstructions. Archaeological applications of this research are becoming increasingly valued for their contributions to the biological and earth sciences. While archaeological datasets are incomplete and oftentimes biased by research, preservation, and/or collection strategies, they have the potential to shed light on much longer-term ecological processes. The growth in more specialized environmental archaeology journals (such as the *Journal of Island and Coastal Archaeology*, *Geoarchaeology*, and *Archaeometry*) (see O’Connor 2001) as well as “cross-over” journals that regularly publish archaeological research (e.g., the *Anthropocene*, the *Holocene*) attest to this fact. Additionally, the increase in environmentally focused archaeological graduate programs of study (University College

London, University of Sheffield, Umeå University, University of Florida, University of North Texas, Texas A&M University, etc.) indicate that archaeological interpretations underpinned by sound paleoenvironmental reconstruction stand to offer invaluable insight about environments that may not have a current analog, but which may arise in the future.

Parallel and Distributed Computing

XAVIER RUBIO-CAMPILLO

University of Edinburgh, UK

Parallel or distributed computing is the action of splitting the execution of a computer program into different simultaneous tasks. The main goal behind this decision is to speed up computationally expensive processes that would take too much time with a single computer.

The popularization of parallel computing has been one of the most important recent developments in computer science. This increasing trend is based on two key advances in the field. First, the first decade of the twenty-first century saw the commercialization of cheap commodity computers with multicore architectures. This change in design meant that standard desktop computers integrated more than one central processing unit (CPU) (currently two or four cores). Second, the development of software able to run tasks in parallel was facilitated by the publication of new protocols and platforms. These tools widened the audience of parallel computing by allowing nonspecialized programmers to exploit the new multicore capabilities. These contributions in hardware and software systems extended the application of parallel computing to a vast array of problems with high computational requirements (Dongarra 2006).

Generally speaking, current parallel computing methods offer a diversity of solutions to the need for high computational requirements. In its basic form they allow any developer to accelerate the execution of computationally expensive algorithms by using a desktop computer. The most advanced methods and hardware infrastructures are able to run in a matter of hours simulations that would take years with a single computer.

The simplest form of distributed computing is shared-memory parallelism. It splits a global program into different tasks executed in the CPUs

of a single multicore computer. The cores are integrated in the same machine, and for this reason they can communicate with each other by sharing information. Shared-memory distribution used to be strongly dependent on particular architectures, but standards such as OpenMP and POSIX have currently made source code independent from the hardware where it is being executed. These standards allow a developer to distribute a program while preventing synchronization issues between the different tasks (e.g., a variable being simultaneously modified by two tasks). A special case of shared-memory distribution is the use of graphical processor units (GPUs). GPUs are designed for graphic processing and integrate thousands of very small processors. While CPUs are general-purpose cores that can execute any type of problem, GPUs are extremely efficient for vector-based operations such as the ones undertaken in 3D processing and machine learning.

Shared memory parallelism is limited by the number and speed of the cores inside a computer node. Any improvement in one of these two factors carries with it a significant increase in the price of the hardware. This cost has a dramatic impact on the scalability of the systems, as the investment needed to handle problems of higher complexity will be prohibitive for most institutions.

Distributed memory is an alternative approach used to parallel computing. It consists of a network of CPU cores with independent memory (i.e., each core can only access its own memory). A system created with this method is able to deal with highly complex problems by increasing the number of nodes connected to the network. However, this scalability comes at a price in terms of software development, as the application needs to organize data-sharing as CPUs cannot directly access information owned by the rest of the computer nodes in the network. A protocol called message passing interface (MPI) is the most popular method to implement this communication. The use of this standard ensures that a program running distributed memory parallelism is platform independent and can be executed in any existing architecture.

Both approaches (shared memory and distributed memory) can be combined in systems implementing hybrid parallelism. Its general design integrates several multicore computer nodes within a common network. The entire system is then used to run software implementing both types of parallelism (e.g., using both OpenMP and MPI protocols). The approach is able to efficiently use all available cores while having high scalability.

Hybrid parallelism is the current standard for applications with high computational requirements. The approach can take many forms depending on the communication network linking the computer nodes. The slowest networks are generally defined as grid computing infrastructures. The nodes comprising this network are connected via standard Internet communication. This solution is cheap and reliable, but it can have significant speed bottlenecks as communication speed is much lower than computing speed up to the point where it could be slower than sequential execution. High-performance computing (HPC) architectures are infrastructures designed to minimize these efficiency issues by integrating the computer nodes within a high-speed communication network. The largest and fastest HPC systems are called supercomputers. They combine the power of hundreds of thousands of CPUs or GPUs in large-scale facilities. These cores are integrated within computer nodes connected by networking systems such as InfiniBand. These high-speed networks ensure that communication between nodes is hundreds of times faster than the Ethernet systems used in standard local networks.

Parallel computing has boosted the use of simulation in scientific research. The increase in computing power has allowed a diversity of fields to deal with more complex problems than were previously explored. Systems that were previously modeled at a single level can now be studied with multiscale simulations. This flexibility allows the researcher to link behavior defined at very small resolutions with global dynamics observed in the studied system. Results improve the understanding of topics as diverse as molecular interactions, contamination dispersal, and epidemic spreads.

Archaeological research has employed parallelism to increase the speed of computationally expensive quantitative methods (see SIMULATION MODELING). Popular spatial analysis

such as cumulative viewshed analysis (see VIEWSHED ANALYSIS) and least-cost path calculations (Llobera et al. 2010) are among the most demanding techniques because they are greedy algorithms. The cost and time required to apply these techniques to particular case studies grow exponentially over the size of the region under scrutiny and the resolution of available data. Data resolution has gradually improved during the last years, but it is difficult to exploit this increase in data quality to generate more accurate results because the time required to run the algorithms is excessive for standard computing. The only solution to this challenge beyond reducing the area or the resolution is to boost up computation time using HPC systems.

Computer simulations and especially agent-based models (ABMs) are arguably the method with the highest computing requirements used in archaeological projects. These requirements are often high for ABMs due to a variety of reasons, including large populations of agents, intensive use of multiple datasets, and complex decision-making processes (Rubio-Campillo 2015). While these issues can affect any model, the most generalized challenge by far is the limitation on the number of simulations that are run for a specific experiment. Simulations are typically explored by changing the values of the input parameters and analyzing under what extent the modeled system reacts to these changes. If the model is stochastic then it also needs to be run multiple times for each set of parameter values because every run will have slightly different outcomes. This process requires anywhere from thousands to millions of runs, depending on the complexity of the examined model, and if it is not properly addressed the analysis of the model will be flawed. As a consequence, limitations on the computational resources can seriously impair the results of a simulation, and this is the reason why most efforts on parallelism within the discipline have been linked to simulation.

The advantages of parallelism for research are not limited to speeding up simulations. The popularization of distributed architectures has contributed to the current popularity of machine learning. This family of algorithms allows the user to train the computer to identify concepts based on predefined categories. The most advanced methods such as deep neural networks would

not be possible without the use of clusters of computers working some type of parallelism. This combination of HPC and machine learning is at the core of the current big data revolution where massive datasets are analyzed to identify large-scale behavioral patterns of complex systems (Upadhyaya 2013).

Current research on parallel computing is focused on decreasing different aspects of its functional cost. For example, the constant increase in the number of computer nodes is generating high energy costs and carbon footprints for state-of-the-art HPC infrastructures. Systems using more efficient CPUs are being developed in order to create green supercomputers (Feng, Xizhou, and Ge 2008). At the same time, automatic code generation and out-of-the-box solutions are lowering the technical barrier of parallel programming. These advances will allow any programmer to develop efficient distributed code, thus extending the impact of parallel computing to any challenge requiring high computational resources (Karlin et al. 2013). It is expected that archaeologists will benefit from these improvements and specifically from the decrease in the need for specialized programming skills. If this can be achieved then projects using simulation and similar computationally demanding methods will be able to develop adequate solutions to their CPU requirements. As a consequence, there will be improvements in both the quality of the analysis and the popularity of these tools within archaeological research.

Photorealism and Digital Reconstruction

CONSTANTINOS PAPADOPOULOS

Maastricht University, Netherlands

Reconstruction: a definition

The word “reconstruction” can be defined as the process of bringing something back to its original state. For example, the reconstruction of a collapsed building would mean that all conditions that existed during the building of the first structure are the same during its recreation; the builder is the same, and s/he has access to all the original materials and knows their exact position in the original structure. If any of these parameters do not apply, then the new building is only a construction in the present providing an impression of how the original looked. This is a simplified example to show that the term “reconstruction” is loaded with a meaning that cannot be supported, at least in archaeological contexts.

The notion of reconstruction did not appear in archaeology with the advent of computer applications (see *COMPUTER APPLICATIONS IN ARCHAEOLOGY*). Since the establishment of archaeology as a discipline, archaeologists have been trying, through fieldwork, study, analyses, syntheses, and interpretations (see *INTERPRETATION*), to reconstruct aspects of past reality which not only are limited to objects and architecture but also include social and cultural process and products. However, life in the past, and especially in prehistory in which written accounts do not exist, cannot be deciphered by people who live and act in distant chronotopes. In other words, archaeologists’ interpretations are formed and negotiated through a series of biases and perceptual leaps due to the different spatial, temporal, and cultural contexts that contributed to the formation of past lifeways and structures. Nevertheless, archaeologists were always trying

to produce reconstructions, and all the media used to realize these, such as text, photography (see *ARCHAEOLOGICAL PHOTOGRAPHY*), and illustration provide a distorted reflection of the past since they attempt to convert the three-dimensionality of the world into a two-dimensional production.

The introduction of scientific methods during the processual phase of archaeology in the 1960s enforced the notion of reconstruction. It was in the post-processual phase from the 1980s onwards that the idea of recreating the past was challenged by the advocates of multivocality (see *PLURALITY AND MULTIVOCALITY*) who argued that there is no single interpretation of the evidence but a social construction in the present highly influenced by the contemporary package carried by the interpreters. During this period—coming about 30 years after the first computer applications in archaeology—three-dimensional (3D) computer graphic visualizations of archaeological sites also appeared and the term virtual archaeology was introduced. The advancement of computational methods and the new technological fetishism reinforced the notion of reconstruction since it was believed that techniques based on automation could achieve accuracy, precision, and objectivity (incidentally the same reasons that governed the wide adoption of photography in archaeology generations earlier).

In the early stages of computer graphics, 3D visualizations of archaeological sites were quite schematic due to the limited computational power and software capabilities, and although the idea of reconstruction was inherent in the processes followed, they were not openly challenged until the advent of photorealism.

Photorealism: a definition

Photorealism appeared in computer graphics in the 1990s when computational power could support an image quality close to or indistinguishable from real life. The term photorealism originated in the United States in the 1960s to

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

DOI: 10.1002/9781119188230.saseas0454

define a style of painting and sculpture that involved the precise reproduction of a photograph. It is often argued that the predecessors of photorealism can be traced back to Dutch paintings of the seventeenth century and the works of Jan van Eyck, who used optical instruments, such as the camera obscura, to help him accurately render on canvas the scenes in front of him.

Photorealism in digital archaeology—the same way as reconstructions—created a long and heated discussion, especially between 1995 and 2005. The main argument was that due to the ultra-realistic nature and high fidelity of computer graphic visualizations, ideas and meanings that rarely derive from archaeological evidence are conveyed. Although the potential of 3D graphics to communicate or experiment with difficult to understand concepts cannot be denied, there have been numerous attempts to counteract their problematic nature.

Ambiguity and transparency in digital reconstructions

Nonphotorealism, which is a technique for rendering 3D models in more artistic and expressive styles, has been proposed as a way to communicate content and explore interpretations free from photographic realism (Roussou and Dretakis 2003). However, when nonphotorealistic rendering is implemented in an attempt to mimic nonphotographic illustration styles, for example, ink drawing, it takes on many of the tropes of photorealism. Other stylistic methods have been proposed in order to highlight the ambiguity of data and allow users to tell what is based on real evidence, what has been restored based on some form of information, or what is pure artistic license. Examples of these are different levels of transparency, digital annotations with the evidence that led to the reconstruction (e.g., field notes, excavation photographs, scholars' interpretations), and visual degradation of uncertain parts (Eiteljorg 2000).

Technical solutions have also been implemented. For example, the creation of interactive visualizations with parameters that can be changed by the user to demonstrate that more

than one option could be valid in a given context and that any changes in one parameter affects the rest. The construction of multiple 3D models that cover all possible interpretations has been followed by many 3D visualization specialists, although it is not often considered the best option due to the time and effort required for their production. The latter has also been accomplished by the use of procedural modeling which can create models in an automated way based on a series of predetermined rules. Other approaches include the quantification of uncertainty by assigning numeric values to the different elements of the models (Niccolucci and Hermon 2006) or a series of theoretical principles, such as the London and Seville Charters, to ensure that best-practice is followed for the visualization of heritage content.

The London Charter in particular and its elaboration by various scholars suggested the introduction of the term *paradata*—that is, information about the processes that humans use for understanding and interpreting particular data (Baker 2012)—to thoroughly document how data lead to 3D models. The latter, however, is utterly problematic, since it presupposes a somewhat linear process of visualization in which there are clear connections between the evidence and the visual output, without taking into account various factors (e.g., perceptual, physiological, technical) which cannot be predicted, identified, and documented in the course of the modeling process. Any stylistic, technical, or theoretical ways to represent archaeological reasoning cannot capture the complexity of the processes to their full extent and will eventually deceive viewers/users into thinking that any ambiguities are limited to those visualized. Archaeology, however, is much more complicated and its multifaceted nature can fit into neither one nor multiple visuals, databases, and guidelines.

Digital reconstructions: analytical tools and knowledge production

Based on all the above, it becomes apparent that reconstructions—either photorealistic or not—have been considered a problematic practice in digital archaeology, despite the fact that, in

principle, they differ very little from the images that archaeologists are used to producing, including illustrations and photographs. However, the power of photorealism and especially physical realism in digital reconstructions as interpretive mechanisms and vehicles of knowledge production has remained underexplored.

Contrary to photorealism that provides a believable rendering of a scene, physical realism provides a prediction of how the scene would look by taking into account the properties of the objects comprising the scene. In the case, for example, of predictive lighting, software is used to simulate the interaction of light with all surfaces, textures, and colors in a scene in order to produce an image closer to what could have been seen in the past. Considering what has been discussed in the previous sections, it cannot be argued that this method can produce reconstructions of the past. Past lifeways were not formed only by lighting conditions but a series of factors, including visual perception, senses, and the psychological state of the observer, which at the moment cannot be modeled in a digital environment. However, such approaches provide a new way of looking into and thinking about data, going beyond the visual appreciation of images. They can work as analytical tools to simulate variables of the past that could not be taken into account by using any means traditionally used in archaeology.

Lighting simulation (see *SIMULATION MODELING*) and analysis (Papadopoulos and Earl 2014) can be used as a heuristic source that has the potential to enhance understandings and interpretations. For example, in the computer graphic simulation of the “ceramics workshop” at Zominthos, the illumination study and the multiple structural models produced (Papadopoulos and Sakellarakis 2014) challenged the original interpretation of the room as a working space, that is, for making pottery, since the lighting values obtained did not indicate that this could be an environment with enough visual acuity that could provide sufficient light to the potter to work on the wheel. This new interpretation was not a conclusion but a starting point for further discussion and elaboration on the possible uses of space that also led to the re-examination of field notes and other excavation evidence.

Similarly to lighting simulation and analysis, computer graphic 3D reconstructions can work

as analytical tools to investigate other properties and parameters of past environments, providing metric data that can inform the interpretive process. For example, visibility analysis (see *VISIBILITY MODELING*) in 3D spaces has provided a new way of analyzing space (see *SPATIAL ANALYSIS*), as well as discussing and understanding social patterns and socio-symbolic meanings (Paliou 2014). Also, structural analysis can help researchers to build multiple structural models and test hypotheses about the validity of architectural reconstructions and their interpretations. Acoustic modeling and simulation is another tool that has moved archaeological inferences beyond the ocularcentrism of archaeology by considering aural experience and discussing perception and the soundscapes of the past. All these approaches have introduced a novel way of dealing with and enhancing spatial concepts by providing metrics that allow the quantification of interpretations while considering multimodal variables and sensory engagements that would have affected human experience. The latter has been augmented by the advent of virtual reality (see *VIRTUAL REALITY MODELING*) which has developed immersive ways of thinking and understanding spatial relationships, adding the sense of presence in the perception and experience (see *PERCEPTION AND EXPERIENCE*) of past spaces.

Although the power of such tools cannot be denied, it cannot be claimed that by using digital reconstructions and formal methods of analysis the past can be reconstructed. However, computer visualizations are not the last and often unnecessary addition to the presentation of a dataset, and if they continue to be merely seen as products, then the whole attempt to incorporate these in the archaeological process will remain a utopia. The sense of authenticity (see *AUTHENTICITY IN VRM*) that these images carry has long been debated, and alternative ways of approaching this by downgrading, blurring, and coloring visualizations have been proposed. Without neglecting the powerful visual impact they have, we should move a step forward, since we have come to realize that different levels of ambiguity are inherent in the nature of archaeology and consequently in the images produced. This means that since there is no way to avoid the

nature of these images, the stimuli that 3D visualizations provide should be used by thoroughly evaluating and critically approaching hypotheses and results. Computer graphic simulations should be employed as a means of visualizing concepts and ideas, and decision-making processes and interpretations. In such a way, interpretations materialized in the form of 3D visualizations become heuristic sources and working hypotheses in the production of archaeological knowledge, becoming part of a never-ending translation process, augmenting perception and providing stimuli to expand the interpretive vocabulary of the archaeological process.

Remote Sensing

SARAH PARCAK

The University of Alabama at Birmingham, USA

The field of remote sensing (see AIRBORNE REMOTE SENSING) in archaeology is growing (Parcak 2008), and has allowed for some of the most exciting discoveries globally since the turn of this century. It covers everything from ground-based systems (magnetometry (see MAGNETOMETRY), resistivity (see ELECTRICAL RESISTIVITY) and ground-penetrating radar (see VISUALIZATION OF GROUND-PENETRATING RADAR DATA)), airborne systems (light detection and ranging (LiDAR) (see AIRBORNE LASER SCANNING AND LIDAR), aerial photographs (see AERIAL PHOTOGRAPHY), unmanned aerial vehicles (UAVs) (see DRONES)) to space-based systems (radar (see SYNTHETIC APERTURE RADAR), satellite imagery (see SATELLITE HYPERSPECTRAL AND MULTISPECTRAL IMAGING)). Archaeologists have debated if remote sensing is now a standard part of archaeology. Given the rapid increase of graduate dissertations and theses, conference papers, grant programs, and academic articles, it appears it is an integral part of archaeology. What is needed presently is a more open discourse on the overall utility of these data, as well as the accompanying ethical issues.

The field of remote sensing has existed for over 100 years, as an early image of Stonehenge, taken in 1908 from a balloon, is considered the first airborne image of an archaeological site. The 1950s saw the growing use of aerial photographs, with early applications of infrared film in the 1960s. Ground-based remote sensing saw major growth during this time as well. The Landsat satellite launched in 1972, and satellite remote sensing articles started to appear by the mid-1980s. Advances in magnetometry and resistivity equipment allowed for more detailed subsurface feature maps in the 1990s, leading to nearly complete ancient town plans. By the late 1990s, archaeologists could access high-resolution satellites

with a 1-m resolution, but at great cost. With the launch of multiple high-resolution satellites ten years later and the availability of Google Earth, in addition to open source processing tools, satellite remote sensing became a low-cost tool for the assessment of ancient landscapes (see ENVIRONMENT AND LANDSCAPE).

Specializing in remote sensing for archaeology often requires specific university graduate-level courses. Archaeologists may take classes as undergraduates in geographic information systems (GIS) (see STATISTICS AND GIS), remote sensing, or landscape archaeology, but will receive advanced training during their graduate work. As it is so landscape- and culture-specific, archaeologists must adapt their approaches and tools over several seasons. GIS and remote sensing software packages are readily available, and with open source GIS tools like the geographic resources analysis support system (GRASS), cost is no longer an issue for researchers. It is not possible to specialize in all forms of remote sensing, so archaeologists tend to choose between ground- and space-based tools. Also, surveyors may join an excavation without extensive previous archaeological experience.

Archaeologists have made major discoveries using remote sensing this century. At the site of Angkor Wat in Cambodia (Evans et al. 2013), archaeologists have used LiDAR, a laser sensor system flown on airplanes, helicopters, or unmanned aerial vehicles (UAVs), to map most of the temple complexes, many of which are beneath dense rainforest. In Belize (Chase et al. 2012), LiDAR has helped archaeologists map thousands of previously unknown Maya sites and features. High-resolution satellites, combined with LiDAR and magnetometry, have revealed a potential amphitheater, roads, and warehouses at the site of Portus (near Rome), Italy (Keay, Parcak, and Strutt 2014). At multiple sites in Egypt, magnetometers have revealed the outlines of ancient cities (Rosenow 2010). In each case, the importance of ground truthing the results must be emphasized. While a feature may be clear from space or airborne imagery,

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

© 2018 John Wiley & Sons, Inc. Published 2018 by John Wiley & Sons, Inc.

DOI: 10.1002/9781119188230.saseas0630

archaeologists must confirm it with survey or excavation. Finally, satellites have helped archaeologists to map hundreds of thousands of looting pits across the Middle East (Parcak et al. 2016).

Now it is possible to ask new questions about ancient sites using remote sensing. Archaeologists can examine ancient human–environment interactions in far greater detail when they know the locations of defunct river beds or ancient sites partly covered by modern towns. They can better plan grant applications with Google Earth, which allows for exploration of sites prior to visiting them on the ground. Regional approaches will vary widely, as LiDAR is not permitted in some Middle Eastern countries, while satellite imagery will not work in much of Central America or Southeast Asia due to vegetation coverage. There is no “one size fits all” approach, as landscapes, seasonality, country permits, access, and cost may affect the types of remote sensing any project may do.

New advances in the resolution of satellite data (now 0.3 m) and its spectral ranges, and the ease of using GIS (with countless online tutorials) are allowing for greater experimentation and the pushing of boundaries. Crowdsourcing efforts like GlobalXplorer (www.globalxplorer.org) are allowing thousands of members of the public to examine satellite imagery and contribute to heritage mapping efforts. Drones now can carry LiDAR along with hyperspectral cameras and multispectral sensors, making it possible to image nearly anywhere in the world at great resolution.

How, then, should we protect and store all these newly collected site data? These and many other ethical issues remain to be debated. The future of remote sensing for archaeology is exciting, but should be approached with caution.

Scanning Probe Microscopy

MICHAEL W. PENDLETON
Texas A&M University, USA

Scanning probe microscopes (SPMs) measure surface properties such as roughness. SPMs include atomic force microscopes (AFMs) and scanning tunneling microscopes (STMs). The development of the SPM or the AFM began with the invention of the scanning tunneling microscope (STM) in 1982 by G. Binnig and H. Rohrer. Initially, the first SPMs were used to measure three-dimensional surface topography. The common trait of many SPMs is that the measurements are obtained with a sharp probe or tip (commonly shaped like a pointed triangle) mounted at the end of a cantilever. The first instruments to show arrangements of atoms on flat surfaces were STMs, but the application of the STM to archaeological samples is limited.

To operate a SPM, the sharp tip is mounted on one end of a cantilever and moved in three directions including the rastering movement in both x and y planes and moved in the vertical direction (up and down in elevation or z plane) very close to the surface to be analyzed. Piezoelectric crystals mounted at the cantilever's other end move the tip precisely in the x and y planes because the crystals can accurately change their shape in response to a computer-controlled electric field. The crystals unerringly raster the tip (in the x plane) in a line from one edge of the sample area of interest to the opposite edge, and then the tip shifts position slightly (in the y plane) to begin another passage over the sample in the x plane (in the opposite direction). These rastering movements (in the x and y planes) are completed again over and over until the tip has traveled across the entire area of interest. The position of the tip in the z plane (up and down) is influenced by van der Waals forces (and other small-scale atomic forces), so the same clearance between the tip and the sample surface

is maintained despite changes in the elevation of the sample surface topography.

Needle movement in many AFMs is precisely plotted by focusing a laser beam on the top of the cantilever. This beam is reflected onto a light-sensitive screen so any movement of the cantilever and tip in all three planes (x , y , and z) is digitally recorded while rastering the sample surface. Computer software can construct a three-dimensional map of the surface by careful correlation of the plotted position during rastering (x and y) related to changes in the z (elevation of surface) position.

Different contact modes in AFM

Many AFMs can be placed into different tip contact modes during operation. During contact mode, the tip of the cantilever gently touches the sample surface as it rasters the area of interest. The topography of the sample causes the tip to move and deflect the cantilever. As the tip contacts the surface and moves along it while rastering, strong repulsive forces (between atoms) cause the cantilever to deflect away from the surface only slightly. But subsequent tip contact with the sample will reduce resolution as the tip is dulled. In non-contact mode, the cantilever tip vibrates (or oscillates) just above the sample surface while rastering. Using a rapid response feedback loop, the oscillation amplitude decreases as the tip approaches the sample. Only rarely would tip contact occur in this mode. In tapping mode, the cantilever oscillates near the surface of the sample, but at higher amplitude of oscillation than in non-contact mode. With a greater deflection signal (the indicator that the surface is near), better topographic control is achieved so a rougher sample surface can be mapped than with non-contact mode. Some manufacturers, such as Park Systems (2016), have introduced a unique non-contact technique that allows tip and sample preservation as well as a very small tip-to-sample distance to provide very good resolution. A vibrating cantilever is controlled in

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

© 2018 John Wiley & Sons, Inc. Published 2018 by John Wiley & Sons, Inc.

DOI: 10.1002/9781119188230.saseas0519

part by both static electric repulsive forces and the attractive force between atoms of the sample. These forces include the equal sharing of electrons for non-polar molecules, the unequal sharing of electrons in polar molecules, and the transfer of electrons in ionic molecules. Depending on the types of bonds existing in the sample atoms, the complex forces at the sample surface interact with the forces of the atoms of the cantilever needle to establish a distance from the sample surface at equilibrium. As the vibrating tip distance to the surface is shortened due to an increasing elevation of the sample surface, the repulsive forces between tip and surface increase, and the increase in force results in an increase in distance. Using vibration amplitude adjusted to maintain a clearance of a few nanometers from the sample surface, any changes in sample elevation are easily recorded as changes in the cantilever vibration frequency because the repulsive atomic forces change the frequency of cantilever vibration. These changes in frequency vibration are digitally transformed into two-dimensional diagrams of surface roughness or three-dimensional maps of the surface. The tip rarely touches the surface of the sample with this system because the high frequency vibration of the cantilever allows very small tip movements to detect surface elevation changes.

Microwear studies of replica and archaeological tools using AFM

Early AFM research was carried out by Kimball, Kimball, and Allen (1995) using the digital software built into the AFM to create three-dimensional top views, surface plots, and cross-section profiles. The differences observed by AFM between surfaces of hafted experimental backed bladelets used to work wood, antler, dry hide and meat for 1 hour each were compared with unworked bladelets from the same nodule. The resulting differences in polish between bladelets as a result of working different materials could be discerned by using incident-light microscopy and hand lenses up to 200 $\times$ magnification. This method was based in part on the early work of Semenov (1964) in Russia and later Keeley (1977) using incident-light microscopy in the West. The AFM was also used to characterize the use of these bladelets using

polish features, which correlated well with the postulated use of bladelets determined using the Keeley method. These results are quite impressive considering that the area that could be effectively scanned (in 1995) was very small, roughly 15 $\times$ 15 micrometers (Kimball et al. 1995).

The software output commonly produced by AFMs such as the Veeco Icon AFM (Faulks et al. 2011) includes not only three-dimensional topographic images of a sample surface, but statistical evaluations of these surface characteristics defined as roughness, skewness, and kurtosis. Roughness is usually quantified as the average of the differences in elevation between the lowest areas of a sample compared with the highest adjacent areas of a sample. If these differences were very great for a sample area, then the sample would have a larger roughness value. Skewness is a determination of the sample symmetry, so that a sample surface having only slightly raised plateaus would have smaller skewness values, but another surface comprising steep peaks and low valleys would have greater skewness values. Kurtosis pertains to the shape of a distribution curve of the roughness values of a sample. The kurtosis for a sample area that approached that of a normal uniform bell curve would be higher than that of a sample area that had greater disparity in the distribution of roughness values.

Experimental microwear pattern analysis derived from experimental tools used to work different materials was compared with the results of analysis of features of microwear polish on Middle Paleolithic (Mousterian) flint tools from Myshtylagty Lagat (Weasel Cave), Russia (Faulks et al. 2011). The microwear on experimental tools was produced by contact with meat, fresh hide, dry hide, bone, wood, and hafting. The wear surfaces of both experimental and Mousterian tools were analyzed using the qualitative approach by Keeley (1977). The wear patterns of experimental tools used for working different materials were described and compared with wear patterns on tool artifacts from the site. Matching patterns on experimental tools were used to postulate the use of tool artifacts. The wear surfaces of both experimental and Mousterian tools at Weasel Cave were also analyzed by the quantitative system of AFM, which determined that meat and dry hide polishes are least developed with smaller changes in roughness (in nm) while

bone and wood polishes are more developed and have larger changes in roughness (in nm). These quantitative (rather than qualitative) values, especially skewness and kurtosis, could distinguish polishes produced by cutting meat versus cutting dry hide, a difference difficult to verify by simply examining roughness or morphology by the Keeley Method (Faulks et al. 2011, 314). Scans of 50×50 micrometers were possible in order to produce three-dimensional surface maps.

Archaeological pottery analyzed using AFM

Using AFM, a non-fired slip (material applied to a pottery surface for the purpose of decoration) was identified covering the ceramic matrix material composed of hydrated calcite and volcanic stone fragments of Zaghe (Iran) ceramics (5100 BCE). This non-fired silica-rich slush could be one of the oldest slips discovered which continuously covers the ceramic matrix. Grain boundaries and the defects due to processes known as sintering by partial smelting were detected by AFM because boundary decomposition and rebuilding processes are readily apparent (Emani et al. 2016, 18).

Laser scanning confocal microscopy is similar to AFM

Laser scanning confocal microscopy is a surface analysis technique very similar to AFM that has also been employed to characterize archaeological lithic materials (Evans and Donahue 2008). A LSCM uses a laser to reflect light only in precise focal planes across the specimen. The laser light reflected away from the focal plane is removed. The focus plane is motorized to move in discrete steps. An image is taken at each focal plane and these horizontal “slices” of the sample are processed so a three-dimensional image of the sample can be constructed. The resolution in each focal plane is 0.12 micrometers and as much as 10 nanometers in the vertical resolution. The LSCM produced 3D images measuring 96×128 micrometers of flint surfaces used to work antler, wood, fresh hide, dry hide, and greasy hide. These images could be differentiated by their method of

creation using standard roughness measurements employed for characterizing surface roughness in engineering. No needle is used in this system, so no contact occurs with the surface (Evans and Donahue 2008).

Using LSCM, the importance of the effect of different workloads on wear development on experimental stone tool surfaces was demonstrated (Stemp, Morozov, and Key 2015). Previous studies tended to relate duration and intensity of use to increased wear effects. Basalt flakes knapped from raw material collected from Olduvai Gorge, Tanzania, were used to cut oak branches with the same number of strokes but with loading levels applied in increments of 150 grams to 4.5 kilograms. Surface wear data were analyzed using area-scale fractal complexity, relative area analysis, and mean square ratios, which indicated that only above roughly 100 grams could a consistent discrimination of worn flake surfaces by the applied workload be made (Stemp et al. 2015).

A good level of agreement was obtained for the assignment of the tool used to produce wear on Monterey chert utilizing either the conventional Keeley method or the LSCM (Stevens Harro, and Hicklin 2010). Experimental tool wear of replica edges of Monterey chert flakes produced by cutting antler, wood, soft plants, dry hide, and meat was analyzed by both these methods, along with unused replica tool edges. The wear edges (and unused interior edges) of Monterey chert tools from CA-SBA-246, an Early Holocene (ca. 9200–8800 BP) archaeological site on the central California coast, were also analyzed with the Keeley method and with the LSCM. Of course, unlike the experimental chert tools, the material that created the wear on chert tools in the archaeological site was unknown. Therefore the type of tool presumed to create wear was assigned based on the agreement between quantitative machine-based LSCM data and qualitative human analysis using the Keeley method (Stevens et al. 2010).

Future directions

While the claims of researchers concerning resolution or the size of the area of a sample that can

be analyzed by a particular technique are correct when published, it should be remembered that these numbers are for specific types of samples, specific research goals, and equipment current at the time of publication. The types of technology, resolution, and software for AFM, LSCM, and other tools used in surface measurement are always improving. New techniques are constantly evolving, so researchers should choose equipment that best matches their scientific goals following a survey of available surface measurement devices and associated software options.

Semantic Web and Ontologies

HOLLY WRIGHT

University of York, UK

The Semantic Web and ontologies can help archaeologists combine and share data, making the data more open and useful. Archaeologists create diverse types of data, using a wide variety of technologies and methodologies. Like all research domains, archaeological data are increasingly digital. In addition, they are often the result of nonrepeatable interventions, either because field methods (such as excavation) result in destruction of the physical resource, or because sampling strategies are invasive and must therefore be limited. These factors combine to make archaeological data nonreproducible in many instances, but also fragile due to the inherent issues of digital obsolescence. Digital archaeological data are therefore often considered primary data, and must be preserved and made available for reuse by future researchers. This obligation has made archaeology an early adopter of open data sharing and efforts to make data persistently available. Since the 1990s, we have seen the advent of digital data archives and repositories with a specialist understanding of how to work with the diverse data produced by archaeologists. The creation of data that are openly and persistently available from disparate sources has also inspired efforts to bring archaeological resources together and make them interoperable. This allows functionality such as federated cross-search of different datasets, and the mapping of heterogeneous data to authoritative structures, in order to build a single data source and facilitate the creation of new knowledge.

Tim Berners-Lee, the creator of the World Wide Web, coined the term Semantic Web. The World Wide Web is of course highly successful, but its structure is based on a “Web of documents” comprised of pages linked together, but without a way to make connections between the

data held within those pages. In addition, Web sites are increasingly powered by databases, but hold data in ways that do not allow connections to be made. Data served in this way are usually referred to as being “siloed.” In 2001, Berners-Lee, James Hendler, and Ora Lassila published their vision for the development of a “Semantic Web” conceptual framework to move from a “Web of documents” to a “Web of data” by creating data in a format that is machine-readable (Berners-Lee, Hendler, and Lassila 2001). In order to do this, data needed to be structured in a new way, so the Semantic Web is associated with a structure called graph data. Graph data are organized into a three-part relationship of subject, predicate, and object, also referred to as a triple. Thus, graph databases are often referred to as triplestores. The data held within a Semantic Web-based triplestore are also commonly known as Linked Data, or when made openly available, Linked Open Data.

When using data, especially shared data, metadata becomes very important. Metadata describes what the data are. For example, if an archaeologist has a spreadsheet with faunal measurement data from an excavation, the spreadsheet might have several columns with numbers in each column. Without the heading at the top of each column stating what the numbers are (e.g., femur length), the numbers have no meaning. The numbers are the data, but the column heading is the metadata, providing its structure and relationships. With Linked Data, that metadata structure is typically created by mapping the data to a controlled vocabulary (which is similar to choosing predefined terms in a relational database), a thesaurus (where the terms also have a hierarchical relationship; which is similar to choosing terms and subterms in a relational database), or an ontology (a more complex way of not just organizing terms but also defining entities, properties, and their interrelationships). Formal definitions of what constitutes an ontology differ, and this is further complicated by the frequent use of the word “ontology” as a general term for describing any of the above mapping schemas for graph data.

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

DOI: 10.1002/9781119188230.saseas0527

Whatever the level of complexity chosen for the mapping structure, this approach requires qualitative agreement that concepts from disparate data sources are acceptably similar. For example, an archaeologist working on one project maps the name of the person who created a field drawing to the concept “recorded by” from an “ontology” describing archaeological fieldwork. When an archaeologist from another project sees this concept within the field recording “ontology” and determines that the definition (also known as a scope note) for the name of the person responsible for field recording matches their own (along with any other parts of the schema deemed appropriate), then the data for the two different projects become “interoperable.” Interoperable data are much more powerful and flexible, as they can be combined and compared more quickly and easily, and allow for new and different interpretations. This concept of interoperability is at the heart of the Semantic Web, but the frameworks and technologies still require archaeologists to agree on the meanings of terms and concepts. This is not always possible or advisable, however, and archaeologists must think carefully and critically about how they map their data, and determine whether the benefits of interoperability outweigh potentially diminishing the diversity or richness of their data and any subsequent research derived from it.

Graph data mapped to an ontology or other type of schema are typically expressed using the Resource Description Framework (RDF). RDF is a data modeling framework for defining the structure and relationships within a data resource. The different types of data to be modeled are typically referred to as classes, and the relationships between the classes are called properties. Classes are things to be queried, assessed, quantified, or manipulated. In archaeology, this might include artifacts, places, soil types, features, or contexts. Properties describe the relationships between resources, like “is fashioned from,” “is in the style of,” “is nearby,” “is parallel to,” “cuts,” or “is cut by,” and so on. The classes and properties of resources are asserted by something called a statement, and a statement in RDF is called an RDF triple.

An RDF triple is two classes joined by a property, and expressed as a “subject, predicate, object” grouping. The RDF triple is the basic

building block of the Semantic Web, and all Semantic Web data can be organized within this simple format. Taking an example from data held in the archive *Stone in Archaeology: Towards a Digital Resource* (University of Southampton 2005), archaeological information expressed as an RDF statement might look like:

Ashford Black Marble *was mined at* Arrock Mine.

In this statement, the subject is “Ashford Black Marble,” the predicate is “was mined at,” and the object is “Arrock Mine.”

RDF can be written in a variety of ways, known as serializations. One of the simplest is called N3 notation. In N3, the above statement could be written thus:

```
@prefix rdf: <http://www.w3.org/1999/02/22-rdf-syntax-ns#>
@prefix sia: <http://dataservice.org/stoneinarchaeology/ontology/>
<sia:Ashford Black Marble> <sia:was-mined-at>
<sia:Arrock Mine>
```

The first line defines the location of the RDF syntax, so any machine processing the data will understand that it is RDF; the second line defines the location of the (entirely fictitious) *Stone in Archaeology* ontology, which allows any machine processing the data to recognize the terms within the ontology and understand the relationships between them. Rather than include the entire Web address for each piece of information, namespace abbreviations are used to create a shorthand which is more human readable: in this case, “rdf” for RDF and “sia” for Stone in Archaeology. Each piece of the triple can then be written using the appropriate prefix followed by the desired value. The third line shows the triple statement “Ashford Black Marble was mined at Arrock Mine.” More information can be easily added:

```
@prefix rdf: <http://www.w3.org/1999/02/22-rdf-syntax-ns#>
@prefix sia: <http://dataservice.org/stoneinarchaeology/ontology/>
<sia:Ashford-Black-Marble> <sia:was-mined-at>
<sia:Arrock-Mine>
```

```

<sia:Ashford-Black-Marble> <sia:was-mined-at>
  <sia:Rookery-Mine>

<sia:Rookery-Mine> <sia:is-a-quarry-near>
  <sia:Bakewell>
<sia:Arrock-Mine> <sia:is-a-quarry-near>
  <sia:Bakewell>

```

This group of statements tells us that Ashford Black Marble was mined at both Arrock and Rookery Mines, and that both mines are in quarries near Bakewell. Note that Arrock Mine and Rookery Mine appear as both subjects and objects. This shows the essential way data link together in RDF. Groups of linked triples come together to form what is known as a “graph.” As graphs are built, new relationships can be inferred. In the example above, it can be inferred that Ashford Black Marble can be found near Bakewell, even though it is not stated explicitly. Inference is one of the key advantages of using Semantic Web frameworks and technologies. In addition to interoperability and inference, data held in RDF and graph format can branch in any direction to form new relationships whenever new data are added, all of which is difficult in traditional relational data structures.

CIDOC CRM is the most commonly used ontology in the cultural heritage domain. It is a formalized set of terms and relationships between those terms, specific to cultural heritage data, and became an official ISO standard in 2006. CIDOC CRM was designed for cultural heritage generally and has become a basis for ontological modeling in the archaeological domain, but does not describe archaeology specifically. One of the first efforts to create an archaeological “extension” of the CIDOC CRM was carried out by Historic England in the United Kingdom. Created in partnership with the University of South Wales, the “CRM-EH” retains coarse-grained interoperability with the CIDOC CRM, and therefore any other data within the cultural heritage sector also mapped to the CIDOC CRM (University of South Wales 2017). The CIDOC CRM Special Interest Group is now collaborating on development of a series of domain-specific extensions, including several relevant for archaeology. These include CRMsci for scientific observation, CRMgeo for spatiotemporal modeling,

CRMba for archaeological buildings, CRMtex for ancient texts, and CRMarchaeo for archaeological excavation. Work on development of these extensions is ongoing, along with discussions about further extensions for other subdomains within archaeology.

A variety of archaeological data resources already make use of “ontologies” and Semantic Web principles and technologies. One of the best examples is Pelagios Commons (<http://commons.pelagios.org/>). Pelagios Commons is a research community working to develop infrastructures for the humanities based on ancient places. This includes the Recogito (<http://recogito.pelagios.org/>) annotation platform where researchers can manage and share their work with other resources connected to an ancient place, and the Peripleo (<http://pelagios.org/peripleo/map>) search service, which allows researchers to undertake map-based searches across a wide variety of interoperable datasets associated with ancient places. Pelagios is also an example of best practice because it uses Linked Open Data from many outside sources—making them interoperable and searchable through a sophisticated Web interface, while also making the data they hold freely available to other Semantic Web-based applications via an application programming interface (API).

There are other online archaeological resources using and/or creating Linked Open Data, but because it is meant to be machine readable, it may not be as obvious to users. Some examples include the Portable Antiquities Scheme (<https://finds.org.uk/>), Open Context (<https://opencontext.org/>), the Alexandria Archive Institute (<https://alexandriaarchive.org/>), the Archaeology Data Service (<http://archaeologydataservice.ac.uk/>), Fasti Online (<http://www.fastionline.org/>), and ARIADNE (<http://portal.ariadne-infrastructure.eu/>). New approaches are also being explored, such as PeriodO (<http://perio.do/>). PeriodO is an authoritative gazetteer using assertion to define archaeological time periods. It does this by aggregating definitions derived from authoritative sources, rather than using global concepts found in traditional top-down “ontologies.” This addresses the problem of “when” always being tied to “where” in archaeology (e.g., the Bronze Age in Sicily may not refer to the

same chronological dates as the Bronze Age in Yorkshire).

The use of the Semantic Web and ontologies within the archaeological domain will continue to adapt, change, and expand, but this is predicated on Linked Open Data resources being persistently available. Future work is likely to include more seamless integration into many aspects of archaeological workflows, such as digital data capture in the field and post-excavation analysis. User interfaces that take greater advantage of the new types of federated queries and inference afforded by graph data and Semantic Web technologies will be created and tested. Tools allowing archaeologists (who are not specialists in digital methods) to more easily map their data and convert it to Linked Data will be improved.

Simulation Modeling

GABRIEL WURZER

Technische Universität Wien, Austria

Simulation modeling is a technique that uses computational experiments for deriving statements about a system. It is typically applied when real experiments would prove unviable (too expensive/dangerous) or the investigated system is a hypothesis in itself. The latter case is reflected in a large body of literature dealing with *artificial societies*, most prominently the Artificial Anasazi model (Dean et al. 2000) which investigates settlement dynamics in the Long House Valley (Arizona, US) between 800 and 1350 CE, establishing what rules led to simulation outcomes that closely resemble the archaeological record. Other examples extending from modeling social change (Doran et al. 1994) over the dissemination of culture (Axelrod 1997) clearly illustrate the versatility of this method beyond its use in archaeology.

Modeling process

When seen as a process, simulation modeling is initially concerned with the finding of a mathematical description of a real or assumed system (*modeling*). The resulting *model* represents an abstraction and formalization of the system; it leaves irrelevant details out and captures its essence mathematically, in the form of explicit rules and parameters that can be translated into a computer program in a next step (*implementation*). In a final step, the program is run repeatedly using different settings for its input parameters (*simulation experiments*). The outputs of the program are then analyzed and used to infer statements about the system. Furthermore, simulation results may be used in an iterative fashion to adjust the system's definition itself, thus establishing a spiral process when applied repeatedly.

In parallel to the aforementioned steps, there are a set of activities which aim at improving the quality of the overall process: *Verification* ensures that the model is implemented correctly ("Is the model developed right?"), while *validation* tries to ascertain that what goes into the model ultimately serves the intended research question ("Is the right model developed?"). A further work step lies in the choice of parameter settings. If the range of values for a parameter is known, one still needs to pick out sensible settings for each experiment (*parameterization*). If the value of a parameter is unknown, one may still be able to determine it by *calibration*: Initially, a value range for an unknown parameter is estimated, either through expert knowledge or simply by guessing. In a next step, the simulation is run repeatedly using values from that range, until it has been sufficiently covered. Parameter values for which the simulation produces outputs in agreement with a predefined ground truth (typically the archaeological record) are then deemed possible values for the missing parameter. All of the assumptions and decisions taken during the modeling process should furthermore enter a detailed *documentation* (see, for example, the ODD (overview, design concepts, and details) protocol by Grimm et al. 2010 for a guideline).

Types of models

Depending on formalization, models are characterized as being either *discrete* or *continuous*. In archaeological simulation, this mostly refers to the formalization of space and time: *Discrete-time* models treat time as fixed intervals (seconds, months, or years), while *continuous-time* models work at an arbitrary resolution. Likewise, *discrete-space* models use a grid, while *continuous-space* models work with arbitrary geometry. A further characterization can be done by regarding the outcome of the simulation experiments: *Deterministic models* yield the same results when executed repeatedly, while *stochastic models* give different results since they depend

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

DOI: 10.1002/9781119188230.saseas0534

on randomness. For the latter, one thus needs to conduct more *simulation runs* for each experiment, in order to arrive at statistically significant outcomes.

When building a model, researchers have to initially choose between two alternative ways of decomposing the modeled system: It may either be split into its basic constituents (*microscopic model*, bottom-up approach) or be described on the highest level, naming parts that are interacting (*macroscopic model*, top-down approach). In each of these two classes there exist a variety of *modeling paradigms*—readily available patterns which are used as a blueprint, each one entailing a specific perspective on the modeled system.

The simplest microscopic paradigm is given by *cellular automata* (CAs), which are both time-discrete and space-discrete: Space is partitioned into a grid in which each cell has a state (e.g., live, dead). In each time step, the CA executes a set of rules for every cell, in order to determine what state it should take in the next step. A famous example of that is given by the update rules for Conway’s *Game of Life* (Gardner 1970), which take the state of a cell’s eight grid neighbors into account. Every live cell having

two or three live neighbors stays live (*survivals*). A live cell having four or more live neighbors dies of overpopulation, and a cell with less than two live neighbors dies from underpopulation (*deaths*). Each dead cell adjacent to exactly three live cells becomes live, as if by reproduction (*births*). Despite having no explicit definition of movement within the rules, Conway’s CA is able to produce patterns that float through the grid, oscillate (see Figure 1a), or stay stable. It is an example of *emergence*—simple behavior on a micro level that results in complex behavior on a macro level. Another example from the social sciences lies in Schelling’s model of segregation (Schelling 1969), which is outlined in Figure 1b: In an initial step, each cell is attributed one of three colours (e.g., white for unoccupied, blue or green for occupied). The update rules state that an occupied cell “moves” to an unoccupied location if surrounded by less than a certain percentage of the same color (note: technically, moving a cell is done by swapping colours). After a number of steps, segregation starts to occur (see right in Figure 1b). The simulation ultimately stabilizes when all cells are surrounded by cells of their own kind.

Figure 1 (a) “Blinker” pattern in Conway’s Game of Life. (Left) Initial distribution of live cells depicted in black; (right) distribution after one time step. (b) Schelling’s segregation model. (Left) Initial population distribution; (right) segregation occurring after a number of time steps. (c) Spatial discretization in agent-based modeling (ABM). (Left) Discrete-space ABM; (middle) continuous-space ABM; (right) mixture with discrete-space environment and continuous-space agent movement.

Extending CAs by moving entities (*agents*) yields the paradigm that is most commonly used in archaeology: *agent-based modeling* (ABM; see left in Figure 1c). Every agent has a state and a number of update rules which are applied in every time step. Such rules look just like CA rules, only they allow for additional interactions (agent-agent; agent-cell, e.g., “If the cell I am standing on is yellow and there is at least one neighboring agent, change position to a cell which is not blue and has no agent on it”). The CA forms the *environment* for all agents, which can act either on themselves (cell-cell, as in classical CAs) or on agents in their vicinity (cell-agent).

The example given left in Figure 1c shows a discrete-space ABM: Agent positions are constrained to cell centers and agent movement really means “hopping” between these. The previously mentioned Artificial Anasazi model (Dean et al. 2000) is an example of such a purely discrete ABM: In every year, the CA calculates the yield as a state variable for each arable cell. Households (agents) are situated in the center of a specific cell (the “settlement”). They have a designated farming spot (different cell) which they “harvest” by (1) deducting a certain amount from that cell’s “yield” state variable and (2) adding that to its own “harvest” state variable. In case the harvest plus any food left in a household’s “store” (also a state variable) is insufficient for the coming year, the household tries to find a new settlement and farming spot, both at the center of a cell. The Anasazi model is a representative of the wider class of models referred to as Sugarscape (Epstein and Axtell 1996), in which agents collect a desirable substance (*sugar*) that has been deposited on a grid. As with CAs, a typical characteristic of these approaches lies in the emergence of complex behavior (e.g., wealth distribution according to power-law in the original Sugarscape model).

There are also continuous-space ABMs that use *maps* instead of CAs as environment (see middle part of Figure 1c). They are typically embedded in—or import data from—a *geographical information system* (GIS) which holds the spatial features through which agents can move freely. These features tend not to have update rules as cells of a CA would; instead, the environment behaves as a passive part of such models, being used for queries (e.g., “If elevation at current point is above sea level, move forward”).

As a third and nowadays most commonly used option, ABMs can be implemented as a mixture involving a discrete environment (i.e., a CA) through which agents can move continuously (see right in Figure 1c). The main advantage over discrete-space CAs lies in the fact that small-scale agent movements can be simulated with greater accuracy (pedestrian dynamics, crowd simulation) and appeal (visualization).

There are scarcely any approaches in archaeological simulation using modeling paradigms other than CA and ABMs, even though some would be quite similar in scope. For example, *discrete-event simulation* (DES) can be used to simulate long-running processes on a micro-level. It is a paradigm that models only state changes (i.e., beginning and ending of an activity), which allows the simulation to skip the time in between. A further paradigm called *system dynamics* (SD) is beginning to be applied for macro-level aspects such as economical flows and population development: It models *stocks* holding quantities and *flows* (changes in quantity over time) between these. In contrast to the paradigms presented earlier, SD is a continuous-time approach, that is, flows theoretically happen in infinitesimally small time steps (*dt*). However, computers will use discrete (but very small) time steps in practice.

Spatial Analysis

KENNETH L. KVAMME

University of Arkansas, USA

Spatial analysis refers to the study of spatial distributions of archaeological and related phenomena. The identification and understanding of spatial patterning has been inherent to archaeology since provenances of artifacts were first recorded in the nineteenth century. Early inquiries were a matter of subjective impression until spatial analysis emerged as a subdiscipline in the 1970s. It has its genesis in the quantitative geography movement of the 1950s–1960s whose methods were later adopted for archaeological problems (e.g., Hodder and Orton 1976). Initially, nearly all spatial analyses rested within the province of mathematics and statistics, with an important side-trajectory that included incipient computer graphics which permitted ancient mapping and visualization of distributions (e.g., the SYMAP program). This duality of quantitative and visual approaches continues today, although in much evolved forms. A second early division was between analyses that focused on archaeological distributions *within sites* versus those that occurred at a regional scale or *between sites*. This division characterizes most applications today, although wider domains are now included, ranging from use-wear pattern distributions on artifacts, often linked with image or residue analysis, to continental or global scales that examine group movements of cultures or cultural elements through time and space. Regional analyses typically examine relationships between settlements (or other areas of human activity) and the social or physical environment, or the nature of how they are located relative to each other, and this division reflects yet another dichotomy fundamental to spatial analysis. First-order effects occur when variations in environment (e.g., soil quality) influence archaeological distributions, while second-order effects occur when interactions between the elements themselves impact their

distributions. Both processes mean that chances of occurrence vary over space, making them “nonstationary” or “inhomogeneous,” which can lead to uniformity or clustering of distributions.

Early work through the 1980s was primarily empirical and statistical. Intra-site analyses examined distributional differences in artifact or faunal assemblages and second-order effects that formed “activity areas” and co-occurrences of tool types, referred to as “tool kits” (summarized in Hietala 1984). Despite issues stemming from boundary problems, nearest-neighbor analyses provided useful indices of relative dispersion or clustering of artifact classes. Local density analysis, Hodder and Okell’s A, and multi-response permutation procedures went a step further, the first by considering all distances within a defined radius of each object, and the remainder by assessing distances between *all* artifacts within analyzed classes to determine spatial association or segregation without boundary issues. “Pure location clustering” referred to a method that identified natural clusters of artifacts, presumed to reflect areas of activity, through the k-means algorithm applied to two-dimensional spatial coordinates. “Unconstrained clustering” identified clusters based on artifact types that consistently occur together within a site, so-named because clusters were unconstrained by shape, size, or density.

At the regional level, a variety of procedures were developed to ascertain environmental and other variables relevant to archaeological site locations, or first-order effects. *Site catchment analysis* (SCA) focused on environmental circumstances within site neighborhoods or “catchments” defined by an exploitation radius of a few kilometers. Differences in resources were argued to influence variations in population, political power, and the like. Other approaches focused on location associations between sites and environment using chi-square goodness-of-fit tests for nominal-level variables such as soil types. For quantitative variables (e.g., distance to water, elevation), measurements made at site locations were statistically compared against measurements at random samples of

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

DOI: 10.1002/9781119188230.saseas0544

nonsites (locations of site-absence); differences implied location tendencies in site placement. Second-order effects were investigated largely through quadrat count methods that assessed clustering or dispersion through comparisons against expectations of a Poisson distribution, but which were highly influenced by scale changes. Modeling utilized trend-surface analyses, which generalized trends (e.g., dates of initial colonization or of the Maya Collapse) across broad regions based on low-order polynomial interpolation functions (Hodder and Orton 1976).

By the 1990s the adoption of GIS technology had a tremendous impact because it increased by orders of magnitude the volume of spatial data that could easily be handled, especially at the regional level. It also encouraged a change in the direction of spatial analysis, which began to lean heavily toward visualization (and away from quantification) because simple overlays of archaeological distributions facilitated recognition of second-order spatial relationships, or they could be overlaid atop environmental distributions (e.g., soils, hydrology) to facilitate discovery of first-order effects.

The initial application of GIS to archaeological spatial distributions was primarily for archaeological location modeling, often referred to as “predictive” modeling (see PREDICTIVE MODELING) (see papers in Wescott and Brandon 2000). This application was largely driven by cultural resource management needs where environmental differences on multiple variables reflected by samples of sites and nonsites in a region could be subjected to multivariate analyses using discriminant functions or logistic regression. GIS map algebra tools permitted mapping of the resultant functions over entire regions to yield probability surfaces for archaeological presence, ideal for management purposes. Other approaches employed Boolean models that mapped the intersection of relevant levels of important variables to indicate likely regions of archaeological presence.

Archaeologists soon began to utilize the potential of other features in the GIS toolbox for addressing various spatial questions (Conolly and Lake 2006). Pathway analysis goes beyond consideration of simple linear distances between places by computing the difficulty or cost of movement through landscapes in terms of “effort” expended

(e.g., calories or travel time), variations in terrain, and impediments to travel (water bodies, vegetation cover). Algorithms ascertained routes that minimized travel costs between predefined points. Resultant nonlinear distances improved the accuracy of proximity variables in settlement location analyses; other studies compared least-cost pathways against known travel routes or settlement distributions.

GIS offered a variety of approaches for spatial allocation, the assignment of spaces to objects, which is ideal for investigating concepts of territoriality. Buffering tools defined areas based on linear distances to delineate circular catchments around settlements, making SCA easy to implement. Tessellations such as Thiessen polygons permitted variations in territory definition. An improvement utilized “weighted Thiessen polygons” where settlement territories were sized according to a quantitative index, such as population. These methods were based on simple geometries and an assumption of an isotropic plane with uniform access or movement costs. Greater realism was achieved by factoring in costs of movement around settlements by considering terrain, vegetation cover, and barriers such as rivers. Results yielded landscape-adjusted territories that were highly variable in shape and size.

Intervisibility studies identified locations visible from a site (or the converse, whether a site was visible from a locus); the resultant mapping is termed a *viewshed* (see VIEWSHED ANALYSIS) (a binary result coded unity where visibility occurs; zero otherwise). A *cumulative* viewshed considers several binary viewsheds and expresses the result as a count or proportion of the number of targets visible from a locus. If targets are burial grounds combined viewsheds have been argued to define a “sacred” space; other approaches have examined whether specific landscape features (e.g., a prominent mountain) were commonly seen. Such studies led to the idea that viewsheds enable study of ancient perception. Others saw viewsheds as only another landscape variable in location analyses by comparing relative sizes of viewshed or whether rival settlements were visible as a defensive consideration. Viewsheds may define social territories: their boundaries have been shown to coincide with regions defined independently by Thiessen polygons, for example.

Since the turn of the millennium, three developments have influenced the direction of spatial analysis: (1) powerful computing became available, even on desktops; (2) a flood of digital information took place as the Internet matured and as spatial technologies developed; and (3) development of a wider climate of easy-to-use and open-access software. Two approaches to spatial problems emerged. One was model-based and grounded in renewed interest in simulation caused in part by open-source software offerings such as *NetLogo*. Many of these agent-based simulations were spatial in nature, determining through complex interactions between multiple agents and decision rules where, for example, settlements might occur (with results compared against actual archaeological circumstances). The other approach was analytical, focusing on GIS-based methods or on new quantitative techniques. The latter include *spatial statistics*: sophisticated and computationally intensive methods developed largely by quantitative geographers that recognize interdependencies in spatially distributed information and how relationships change with spatial scale. Kernel density analysis, a form of neighborhood weighting, permitted generalization of spatial distributions that clarified patterns in graphical plots. Ripley's K (and related indices) enabled the formation of conclusions about clustering or dispersion of point patterns over a range of spatial scales. Global statistics, whether measures of spatial autocorrelation or based in multiple regression, were replaced with local indicators of spatial association and geographically weighted regressions, for example. Their adoption has been facilitated by open-source or free software such as *R* and *GeoDa*. Increasing quantitative sophistication is illustrated by superior methods for cluster detection that avoid the shortcomings of earlier approaches. Deficiencies in Ripley's K are even challenged by replacing its inherent Euclidean geometries with more realistic cost-of-travel distances to quantify inter-point relationships (see papers in Barcelo and Bogdanovic 2015).

GIS applications pertinent to spatial analysis have become more thoughtful and expanded into new domains (see *VISIBILITY MODELING*). In viewshed studies, the limitations of human vision have been considered through Higuchi and fuzzy viewsheds. With increased computational power,

the amount of land visible from *every* point in a landscape permits analyses of settlement location relative to view quantity. Viewsheds have also been applied to within individual structures to assess how they were intentionally constructed to restrict and channel vision and experience. Least-cost pathway analyses and the availability of large regional databases have addressed continental-scale migrations. Computationally expensive "from everywhere to everywhere" approaches now generate travel networks without pre-specified origin and destination points, giving a "neutral view" that indicates where travel was most possible in a region and which have been shown to coincide with known routes and settlements. At a within-site level, pathway analyses have expanded into urban settings or individual buildings. This work is often associated with "space syntax analysis" (see *ISOVIST ANALYSIS*), which assumes that spaces are shaped by social relationships that can be analyzed by reduction to a network of components represented as maps and graphs describing connectivity and integration.

Other recent computational methods include network analysis (see *NETWORK SCIENCE*), which detects patterns of relationships between subjects of interest in complex systems. Rooted in graph theory, it becomes a spatial method when subjects have geographical position represented by nodes (settlements, regions) and the links (trade, alliances) between them. Studies have shown relationships based not on spatial proximity, but according to social connectivity, where links cause certain archaeological occurrences that can be realized by mapping them.

Advances in spatial technology are changing how the data of spatial analysis are acquired (Comer and Harrower 2013). Global positioning systems (see *GPS (GLOBAL POSITIONING SYSTEM)*) routinely capture thousands of coordinates from field mapping projects. Multispectral classification of high-resolution air and space data can define settlements, mounds, and other archaeological features. Advanced pattern-matching algorithms identify regular geometric and anthropogenic shapes from air and space imagery, and mounds and depressions from light detection and ranging (lidar) data (see *AIRBORNE LASER SCANNING AND LIDAR*). These technologies also yield new kinds of information for analysis such as

mound or borrow pit volumes from lidar, or the definition of “anthropogenic areas” revealed by spectral characteristics or geophysical responses.

Structure from Motion

SUSIE GREEN

University College London, UK

The term structure from motion (SfM) refers to the perception of three dimensions when the viewer is moving through space, as we do when we walk around a sculpture to understand its form. When a subject is captured using SfM the movement is usually represented by a series of digital photographs taken from different points. These are processed by computer software to create a point cloud representing the surfaces of the subject, which can be further refined to create a virtual 3D model.

SfM is a type of computer vision technology, using computers to visualize the world, which is driven by research in robotics and autonomous vehicles. The roots of SfM are in photogrammetry and stereophotogrammetry (see PHOTOGRAMMETRY AND STEREOGRAMMETRY), but the cameras used for SfM do not need to be calibrated. The process consists of several discrete steps which require an enormous number of calculations that are only made possible by modern advances in computing. The source photographs must be numerous enough to capture every surface of the target in three or more images and these must be recognizable from one image to the next. The features are analyzed by a scale invariant feature transform (SIFT) to find distinctive key points, which are matched across multiple photographs, then passed on to a process known as bundle adjustment. Bundle adjustment uses the focal length and the size of the camera's photographic sensor which can be derived from the meta-data tags stored in digital images, so it is important that the original photographs are used. Starting with a well-matched pair, lines of projection are calculated between the camera positions and key points. Each image is added incrementally and where it does not fall within the expected parameters it is rejected. As each image is added, the time taken to compare it

increases exponentially and most SfM software uses a system to break up the calculations into smaller parcels. The result is a collection of points representing the locations of the key points and the cameras from which the photographs were taken. If the matches are poor, more photographs can be added at this stage or the software can be asked to consider more key points.

The exact technique used next varies depending on the software. Some commonly referenced techniques are pairwise depth map computation, which uses triangulation to calculate the distance of a point from the camera, and patch-based multi-view stereo (see MULTI-VIEW STEREO) in which features are matched across several images and then expanded to include the surrounding pixels. The result is a dense point cloud representing the surfaces of the subject which can be converted into a 3D model.

In order for features to be matched they must be clearly visible in the photographs. A common reason for failure is grain or blurring caused by low light which can be overcome through the use of a tripod. Excessive digital compression artifacts can also lead to poor-quality results. If lighting is inconsistent across the photographs the features may not match correctly; the best conditions are bright but overcast natural light. Reflective or featureless surfaces are not suitable for SfM, but this is not usually a problem in archaeology.

The positions of cameras and points calculated by SfM have an arbitrary but uniform orientation and scale. In order to derive metric data from the point cloud it must be georeferenced using control points. Most SfM software will include a tool for adding control points and transforming the point cloud to the correct scale and geographical location. More control points will give a more accurate result, but the accuracy of the points in a point cloud is dependent on the accuracy of the control points. However, any errors are generally consistent across the scene, and the relative positions and precision of the points is good. A number of papers that have investigated the accuracy of SfM conclude that while not perfect it is sufficient for most purposes required by archaeologists (De Reu et al. 2013).

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

© 2018 John Wiley & Sons, Inc. Published 2018 by John Wiley & Sons, Inc.

DOI: 10.1002/9781119188230.saseas0559

The point cloud produced by SfM is similar to light detection and ranging (LiDAR) (see AIRBORNE LASER SCANNING AND LIDAR) and laser scanning (see LASER SCANNING), and consists simply of a list of points with color, position, and a value for surface normal, a vector which represents the surface direction. These can be used to produce a 3D model with a surface made of triangular polygons. The source photographs are projected onto the model to create a high-resolution texture that can be applied to the surface. Further processing allows a georeferenced orthographic image to be rendered from any direction, and an equivalent digital elevation map (DEM) to be created by writing the distance from the camera plane to the points on the surface.

“Bundler: Structure from Motion for Unordered Image Collections” was developed by Noah Snavely, based on the project “Photo Tourism: Exploring Image Collections in 3D” to exploit the large number of images that have been uploaded to the internet by the public. Snavely, Seitz, and Szeliski (2006) were looking at ways in which they could make sense of this huge amount of data. Their solution was to arrange the images in 3D space as if seen from their real-world camera positions. The ideas developed in “photo tourism” were adapted to create Microsoft’s Photosynth, which allows the creation of a low-density point cloud from source photographs. The earliest SfM software consisted of a number of scripts linking open-source versions of the core processes. One of these, open source photogrammetry, was released as part of the ArcheOS operating system and designed specifically for archaeologists. VisualSfM was the first fully functional SfM software to feature a user interface, and is free for noncommercial and academic use. Autodesk’s 123DCatch is another free software that uses cloud-based computing to process the photographs. The increasing awareness of SfM in archaeology, as well as its adoption for geographical survey and by the film and video game industry, has led to an increasing number of powerful commercial software solutions. The most notable of these is Agisoft’s Photoscan, a mid-range-priced software with a speed and ease of use that has made SfM a mainstream solution for a growing number of archaeologists. The entire SfM process including production of

models, georeferenced orthophotos, and DEMs can be performed inside Photoscan.

As an archaeological tool, SfM has potential for both recording and investigation. From its earliest employment by archaeologists it was identified as having the capacity to record information that would otherwise be lost during excavation (Doneus et al. 2011). As SfM software becomes more sophisticated its speed and accessibility makes it increasingly feasible to deploy it on site and capture a 3D model of the surface of each context before it is removed, without significant impediment to the process of excavation. The human interpretation of features cannot be replicated by computer vision, but SfM can be used as a complement to traditional plan and section drawing aided by total station (see TOTAL STATION) or differential global positioning system (DGPS). The models created by georeferenced point clouds are suitable for use in 3D geographic information systems (GIS) (see STATISTICS AND GIS), where they can be used, for example, to calculate volumes and visualize negative contexts. The creation of 3D models and georeferenced orthographic images while the excavation is in progress can help archaeologists in their interpretation of features and inform their ongoing course of action (Dell’Unto 2014).

SfM is a good way to capture the complex 3D shape of standing structures, making sense of the plan of a building that is not easily apparent from the ground. The model can be virtually split into cross-sections to examine the volume of the structures and can be used by conservationists to highlight weak points where problems may occur. Repeated models can be used to monitor changes in a building structure over time.

Aerial photography (see AERIAL PHOTOGRAPHY) has a long history of use in photogrammetry, and is an obvious candidate for SfM. The evolution of SfM has been mirrored by the development of low-cost camera-carrying drones (see DRONES), and archaeologists have also been able to achieve good results from light aircraft, cameras lifted by kite (KAP), and balloons (Verhoeven 2011). The resulting point clouds can be compared to the height maps created by LiDAR, with the added advantage that they contain color information. When combined with ground control points they can be used to

create georeferenced digital elevation maps and orthophotos which are precisely aligned. The density of information can reveal subtle features that are invisible to the observer at ground level, but it should be noted that unlike LiDAR, SfM is unable to penetrate vegetation, and therefore is less suited to areas with a lot of ground cover.

Surface information can also be acquired at the macro scale. SfM models can reveal slight deviations in the surface of objects, such as marks or engravings on stone. There are a number of treatments that can be applied to a 3D model to enhance surface detail. One of these is ambient occlusion which simulates light being shone evenly onto an object from all directions, as if from an overcast sky. Areas that are occluded such as small depressions in the surface receive less light and show up as darker areas (Spring and Peters 2014). Another is cavity mapping, which highlights concave surfaces. To further enhance surface detail, an SfM 3D model can be used to create virtual reflectance transformation imaging (RTI). Here a collection of orthophotos is created, each with a single light shining onto the surface from a grid of points. The RTI is then produced using these images instead of photographs.

Future developments of SfM are likely to address the long processing times and usability of the software. It is still prohibitively slow to create detailed point clouds of a large area which means that for archaeological sites and buildings the photographs must be processed and georeferenced in separate groups, then combined into a single scene. The development of mobile GIS (see MOBILE GEOGRAPHIC INFORMATION SYSTEMS (MGIS)) bringing digital recording into the field raises the potential of a more active role for SfM in facilitating the organization and planning of excavations. It should soon be possible to develop software allowing archaeologists to build up 3D models in real time as they take photographs. This would overcome the problem of poor photographic coverage that is only discovered when the subject can no longer be accessed. Immediate integration with 3D GIS would allow archaeologists to trace plans directly onto orthographic images of features, saving the time-consuming task of measuring every feature, and allowing them to concentrate on interpretation.

Structured Light Scanning

CHRISTOPHER BEGLEY

Transylvania University, USA

Structured light illumination (SLI) is a category of techniques for extracting three-dimensional (3D) surface information from target objects, and is widely used in scientific, industrial, commercial, and entertainment applications at a variety of scales and resolutions. SLI involves the projection of a known pattern onto the surface of the target object and relies on optical triangulation to make depth measurements and 3D data acquisition possible. Visible light, infrared light, and laser light have been used in the projection of these patterns. A calibration process provides the baseline data that define any unknown triangulation parameters and allow for the depth to be known for each pixel in the camera. There are a variety of pattern types that can be used: single-dimensioned lines, two-dimensioned stripes, grids, or dot matrices (Chen, Brown, and Song 2000; see Figure 1).

SLI actively projects light into the scene, which is different from passive 3D techniques such as photogrammetry or from stereoscopic methods that use the available ambient light (see IMAGE-BASED 3D MODELING and STRUCTURE FROM MOTION). By projecting the pattern on the target, active 3D imaging techniques generate data from all parts of the target, whereas passive 3D techniques do not work well on flat or featureless targets. Because of this, active 3D imaging techniques like SLI will generally have greater accuracy, precision, and resolution than passive techniques.

SLI systems typically include a computer or other processing unit tethered to a camera and a projector. Recent innovations include scanning systems that are decoupled from the computer, allowing for smaller, lighter, and more robust scanners that can be taken into remote and hostile environments, including underwater (e.g., Crane et al. 2010; see Figure 2).

To use SLI, the projected pattern needs to be the main luminous source of a target object, in order to get proper contrast for pattern differentiation. In practice, this means that ambient light, typically sunlight, can pose a challenge to SLI scanning. Minimizing ambient light by darkening a room, by shielding or covering the target, or by scanning at night or during periods of low light may be necessary if one wants to generate high-quality data.

SLI has been used to generate 3D data at various scales, from small objects such as fingerprints or computer microprocessors to large targets such as progressive assembly facilities for manufacturing. The scale of the application has implications for the requirements of the projection system, as creating sufficient pattern contrast while projecting a large pattern will pose different challenges from projecting a pattern onto a very small target. In archaeology, most SLI has been focused on objects that are rather larger targets, for example excavation units or entire sites.

Commercially available SLI systems vary greatly in price and capability and can be divided into professional (or metrological) systems, which in 2017 ranged from around US \$10,000 to over US \$100,000. The resolution and accuracy of these units vary with the scale to which the technique is applied, but resolution of a square meter scan can be less than 20 micrometers, about the diameter of a thin human hair. Resolution can be much greater when the target area is smaller, down to one micrometer.

Consumer versions of SLI scanners are increasingly available, now on smartphones and very commonly as motion capture input devices for video games. These systems are much less expensive than the metrology-grade systems, typically in the hundreds rather than thousands of dollars for the professional scanners. Accuracy and resolution will be much lower than in the metrology-grade systems, and have typically run in the range of a centimeter, depending on the scale at which the system is being used. Most consumer-level SLI systems are used at room scale or as input for robotics, not for measuring

Figure 1 Structured light scanner in use.
Source: Author.

Figure 2 Prototype of an underwater structured light scanner.
Source: Author.

or recording the details of objects. The utility for archaeology would be at a similar scale, possibly for scanning a site, a large feature, or an excavation unit rather than for use at the object level.

In archaeological applications, SLI systems have been used primarily for object-level applications, for example applications in faunal analysis, lithic analysis, ceramic analysis, and the documentation of features such as petroglyphs (e.g., Manzano, Means, and Begley 2016; Crane et al. 2010). Passive techniques such as photogrammetry are currently preferred for site level applications, owing to ease of use, cost, and resolution needs. The intended use of the data is also a factor. The requirements in terms of accuracy and resolution will be different if the goal is to generate metric data from what they will be if the use of the 3D image is for presentation to the interested public on a website.

While SLI generates higher-resolution and more accurate 3D data than passive techniques in most cases, there are some significant challenges to archaeologists using SLI systems.

The metrology-grade systems are very expensive, and this may be prohibitive in many instances. Consumer-grade SLI systems are much less expensive, but may not offer the resolution or accuracy required, or may not offer significantly greater accuracy or resolution than passive 3D systems.

SLI systems are sensitive to ambient lighting. This may require special steps to ensure adequate pattern contrast for suitable 3D data. Inside a building, this is easily mitigated by darkening the room. Outside, or in environments where darkening the area is not an option, archaeologists may need to shield or cover the objects being scanned. When this is not possible, it may be necessary to perform the scans at night. This may raise safety concerns owing to limited visibility, or access at night may be problematic for other reasons.

While in most cases SLI scanning generates more accurate and higher-resolution data than passive techniques do, especially when the target is flat, smooth, or otherwise featureless, there are certain surfaces that pose a challenge for SLI systems as well. Transparent or reflective surfaces can be difficult to scan, as light may be reflected or otherwise affected in ways that interfere with

an accurate interpretation of the distortion of the pattern on the surface of the target object.

Finally, portability and durability may be an issue. While some rugged, lightweight, and easily portable systems exist (e.g., Crane et al. 2010), most professional-grade SLI systems are not suited for use in remote or hostile environments and are confined to laboratory or museum use, or to use on sites that are easily accessible.

Three-Dimensional (3D) Facial Reconstruction

CICERO ANDRÉ DA COSTA MORAES
and PAULO EDUARDO MIAMOTO DIAS

Brazilian Team of Forensic Anthropology and
Odontology (EBRAFOL), Brazil

Three-dimensional (3D) facial reconstruction or 3D facial approximation is a technique that approximates the face of an individual based on anthropological data regarding context and profile information, such as sex, age, ancestry, individualizing features, and pathologies. It may be applied in archaeological, museological, educational, and forensic contexts. In the field of archaeology, this technique has been used to generate visual interpretations of collected data, such as the facial reconstructions of King Tutankhamen, Queen Nefertiti, Simón Bolívar, St. Anthony of Padua, and St. Rose of Lima (Verzè 2009).

The technique consists of modeling the approximated face over a skull or its replica. Population-specific soft-tissue thickness data (from cadavers or living individuals) may be used as a reference to aid the reconstruction work. Markers placed on cranial landmarks assist the modeling phase, and some of the facial muscles and other structures may be reconstructed to enhance the individuality of the reconstructed face. For a thorough analysis and understanding of a cranium's main and specific features that may influence its facial appearance, an integration of specialists from different fields is desirable (e.g., forensic anthropology, forensic dentistry, head/neck surgery, pathology, forensic art) (Moraes, Dias, and Melani 2014).

The first publications in this field date back to the late nineteenth century. Examples of facial reconstructions from this period include the one of Johann Sebastian Bach, coordinated by Swiss anatomist Wilhelm His, in 1895 (Verzè 2009). Three main methods were developed during what might be termed the scientific

period of the technique's application. In 1920, Russian anthropologist Mikhail Mikhaylovich Gerasimov's method relied upon meticulous reconstruction of soft tissues from osteological anatomy. In the late 1960s, Americans Betty Pat Gatliff and Clyde Snow used a method that uses tissue depth markers as guides to sculpt the face. In the early 1970s, United Kingdom-based experts Richard Neave and John Prag integrated tissue depth data with anatomical reconstructions of the main structures that form the facial wireframe in order to perform approximations. These techniques became known as the Russian, American, and British methods, respectively, and were applied to a number of historical and forensic cases (Verzè 2009).

In referring to 3D reconstruction, it must be acknowledged that a variety of different materials and equipment may be applied to carry out this technique. Manual methods can be performed with modeling clay, while computer-aided techniques use digital tools, which may be semi- or fully automated. Technological advances and operational needs encouraged experts and investigators to develop the rebuilding process for digital systems using 3D computer graphics based around skull replicas obtained through computed tomography (CT) scans (see COMPUTED TOMOGRAPHY), laser 3D scans (see LASER SCANNING), and photogrammetry (see DIGITAL PHOTOGRAMMETRY). Conventional manual techniques carried out in virtual environments use software for modeling and animation, such as 3D Studio Max, Maya, and Blender 3D software (Figure 1). Open source software applications represent an alternative to commercial programs, which might help make these tools available to more investigators worldwide (Moraes et al. 2014). Recently, genetic analysis also has been used to estimate individual biological profiles and generate automated computer-aided 3D facial reconstructions. It is clear that this will form a key future research area (Claes et al. 2014).

Three-Dimensional (3D) Printing and Additive Manufacturing

ALISTAIR GALT

Independent researcher, UK

Three-dimensional (3D) printing, also known as additive manufacturing, is a collective term for a variety of closely related manufacturing and prototyping techniques involving the creation of a three-dimensional mesh file of an object's representation in the real world. This process was known as rapid prototyping, and around the world as automated fabrication, solid freeform fabrication, layer-based manufacturing, stereolithography, or direct digital manufacturing (Gibson, Rosen and Stucker 2014). Originally, additive manufacturing was developed with polymeric materials, waxes, and paper laminates, although a wide variety of materials can be used to create the model, such as plastic, metal, nylon, and glass. All modern additive manufacturing processes rely on the conversion of the mesh to a .stl (stereolithography) file, which describes the external closed surfaces of the original computer-aided design (CAD) model, and forms the basis for calculating the layers (Gibson et al. 2014). Once the file is input into the additive manufacturing machine and the parameters adjusted accordingly, the model can be built. Once completed, though, some cleaning (post-processing) may be required on some models before use: for example, removing support structures for overhangs. Some methods require more post-processing than others, such as cleaning off support structures, post-curing (exposing the model to a higher temperature to maximize some of the material's properties), and finishing, which can affect the final model's appearance and properties.

Additive manufacturing contrasts with machining a model, which subtracts materials from a block of raw material (Gibson et al.

2014). There are some processes where it is still preferable, for the sake of quality, to use machining techniques with certain materials over additive manufacturing. However, depending on the complexity of the model, additive manufacturing may be faster than other methods and is generally safer to use. Forging (also known as a formative process) is the other manufacturing alternative, where the material sets in molds. Forging is cheaper in some cases, but not as accurate. Additive manufacturing models also have many advantages over a drawing of an object (Gibson et al. 2014). Although the drawing is faster, easier, and cheaper to create, the model is in three dimensions and is much more representative of the final product.

Additive manufacturing methods can be broadly split into three groups: liquid, solid, and powder (Chua and Leong 2017). The main differences between these methods are the materials used, the creation time, and the accuracy of the models. Some methods involve a bed which moves as the model is created; others use a moving nozzle. The most accurate methods are rarely seen outside of high-end engineering industries such as aerospace and bioengineering. The most familiar method is known as filament printing. This normally involves a static bed of metal, with a moving head that is fed with a plastic filament that is normally polyvinyl alcohol (PVA), polylactic acid (PLA), or acrylonitrile butadiene styrene (ABS) prototype plastic. This method is relatively quick, although it is the least accurate method, having an error up to 5 mm. Therefore, this method is used in situations where accuracy is not a key consideration, such as for scale models for use in a classroom.

Liquid-based processes generally use a vat of photocurable resin, although other methods can jet drops of liquid photopolymer into a tray via a printhead (Chua and Leong 2017). The archetype of liquid-based processes is stereolithography, which builds up parts by using a vat of photocurable liquid that photopolymerizes when exposed to a laser, creating the shape one layer at a time. The method requires a support structure, and

although it is good for prototypes, it is prone to errors arising from the corrosive nature of the solvents used to remove the supporting structures and requires a significant amount of cleaning, post-curing, and finishing. Polyjet printing is similar to a conventional inkjet printer but uses an ultraviolet light source to dry the ink. This method can involve a great variety of materials but requires a water source. Multi-jet modeling, also known as CMJR, is similar to an inkjet printer but applies a thermopolymer material in three dimensions. The variety of materials one can use with multi-jet printing is limited. A lesser known technique is two-photon polymerization, which can build 3D structures without building up the model layer by layer. This involves firing a laser at photons which polymerize only when they simultaneously absorb the energy from the laser.

Physical methods use wires, filaments, rolls, or pellets delivered through a printhead, such as in filament printing, which is a simplified example of fused deposition modeling. This method heats thermoplastic material to a semi-liquid state and extrudes the material to the required area. It is a slow process, and has a restricted accuracy caused by unpredictable shrinkage as a result of the semi-liquid material re-freezing, but it can produce a large volume model with functional parts. Selective deposition lamination, or SDL, uses paper as its main material in small quantities. It applies adhesive droplets to the paper, using a laser cutter and knife to remove the excess material. This method creates relatively high resolution models for low cost because of the materials involved. It also creates low strength models with a small build volume. This is a preferred method for creating scale models of cities by planners and architects at a low cost. Physical vapor deposition printing uses stencil shadow masks to pattern thin films on a substrate. Sometimes this method involves releasing pulses of high electrical current applied to a skimming metal bed. It is considered the least efficient but most accurate method in manufacturing, with a tolerance of 0.005 mm; generally high purity metals such as copper, gold, nickel, and tin are used. Often this method is used for electronic devices, circuits, and systems, as this process keeps the properties of the metals. Laminated object manufacturing uses large sheets of metal, which are laser-cut into the required shape, and bound to

the next layer by a roller. It is low cost and is compatible with commercially-made sheet metal, although the size of the layers is much larger than other methods, and significant post-processing is often required (Bhushan and Caspers 2017). A lesser known physical method is electron beam additive manufacturing (EBAM), which uses a beam that melts metal onto the surface of the part. While this method can only be used with a very limited number of metals and overhangs are not possible in the model, it is low cost and easy to switch between metals.

Methods using powder-based materials melt the powder into the predetermined pattern in differing layers. Some plastics, such as mobile phone covers, are manufactured with a mold made of a powdered method because it is a good compromise of cost and materials, although the machinery is often cumbersome. A number of powder-based methods exist, some of which share characteristics with liquid printing, and others with physical printing, such as colorjet printing (Bandyopadhyay and Bose 2015). The oldest method in use is known as selective laser melting, which shares its origins with vacuum casting. The main difference between selective laser melting and selective laser sintering is that melting produces an almost 100 percent dense model, as opposed to just a shell, which means the final model is more accurate and stronger than sintering methods. Selective laser sintering is a high-quality but slow process, which is used for producing the tools used in forming and shaping sheet metal. Colorjet printing creates 3D prototypes by solidifying layers of deposited powder using a liquid binder. It can produce models in color, although colorjet printing produces less functional parts and has a poor surface finish in relation to other powder-based methods. Generally, these models are also weaker than selective laser sintering models. Sintered laser, or selection laser sintering, utilizes a high-powered laser to fuse small particles of material. During the process, the bed upon which the build is resting is repositioned, lowering by a single layer of thickness. This method is used for working with metals like titanium for creating very high-quality chess pieces, as well as welding metal to itself in a vacuum. The machinery is very expensive to purchase and complex to operate, and as such is rarely seen outside of the aerospace industry.

The most common application for 3D printing in archaeology is for scale replicas of sites and objects. As they require digital meshes, it is possible to use a 3D mesh from many digital methods, including photogrammetry, laser scanning (see AIRBORNE LASER SCANNING AND LIDAR and LASER SCANNING), and X-ray tomography (see X-RAY TOMOGRAPHY). These meshes are often created in a purpose-built software package (see IMAGE-BASED 3D MODELING). Furthermore, it is possible to reverse-engineer a CAD model (Gibson et al. 2014), such as using photogrammetry or a laser scan of a model to create a printed model of the original object. The reconstruction of cuneiform tablets, Roman tools, and the broken ceramic lion from Nuzi, Iraq, at Harvard University are examples of reverse-engineering an existing object by using photogrammetry to create the mesh of the model, then to extrapolate the broken parts into a single model, and printing the final model with a CNC-machined foam. This method of additive manufacturing is technically known as negative manufacturing, although the other processes involved can all be used in additive manufacturing. It is also possible to use additive manufacturing to create custom-built equipment for archaeological purposes, such as unmanned aerial vehicles. This equipment is often used for mounting more specialized equipment such as cameras purposes. The custom-made nature of these applications means that when commercially produced, these products can be significantly cheaper than their counterparts, or solve a long-standing problem, such as attempting to employ multimode and multichannel radar architectures within the same radar machine (Traill et al. 2014).

Other sectors that employ additive printing methods include the biomedical industry, where additive manufacturing can produce personalized prosthetics, organs, and skin replacement treatments. Printing of biological materials relies on specialized liquid printing methods that have to be used in sterile environments where a variety of cells can be randomly seeded on printed structures so that they can grow and multiply (Carlier et al. 2016). Oxygen must be able to access the mesh at all times; only biodegradable plastics can be used to hold the mesh together with hydrogels to encourage cell growth and multiplication (Kang et al. 2016). The tolerance for error in

bioprinting is in the micrometers, and uniquely there are risks in rejection and inflammation of cells, so scaffolding cannot be used in most cases as they may increase these medical risks.

Many educational establishments and schools have filament printing devices for outreach purposes and building concept models. It has been noted that additive manufacturing technologies have the potential to improve education by giving a sense of empowerment to the users (Shelley et al. 2015).

As the industry grows, it is expected that other sectors will look to employ additive manufacturing in new ways, potentially disrupting the way we approach archaeology with new solutions to long-term problems, and with increased collaboration with the engineering industry.

Viewshed Analysis

LAURA TOMA

Bowdoin College, USA

Introduction

Modeling and computing visibility on terrains is a fundamental problem in terrain analysis and is at the core of numerous applications. With terrain data available from light detection and ranging (LiDAR) technology at 2-m resolution and below, modeling visibility on terrains has the potential to offer incredible accuracy. At the same time, handling large amounts of data poses challenges to the algorithms, which can run for days or longer before producing a result. Analyzing and optimizing the efficiency of algorithms is crucial when dealing with large amounts of high-resolution data. This entry surveys algorithms for the computation of viewsheds on terrains, with emphasis on the computational complexity. For a description of the applications of viewsheds in archaeology we refer to “Visibility Modeling” (see VISIBILITY MODELING) in this volume. We will start by introducing some terminology and definitions.

Terrain models

Modeling visibility on terrain assumes we are given a *digital terrain model*, or, in short, a terrain model. In practice, digital terrain data come as a discrete set P of 3D sample points, $P = \{p_1, p_2, \dots, p_n\}$, where each point is specified by its latitude, longitude, and the measured elevation of p_i , which we denote by $z[p_i]$. A terrain model consists of a set of sample points together with an *interpolation method* that describes how to obtain the elevation values for points other than the sampled points P .

The two most commonly used terrain models are the *grid* and the *TIN* (triangular irregular network). On a grid terrain the elevations are

sampled with a uniform grid. Grids can be used with a variety of interpolation methods, such as linear, bilinear, or nearest neighbor. A TIN terrain consists of an irregular sample of points, which are connected in a triangulation. The elevation of an arbitrary point on the terrain is interpolated from the triangle that contains its latitude and longitude. Put differently, a TIN models the surface as a mesh of triangles. Typically, the triangulation forms a Delaunay triangulation when projected on the horizontal plane. Both grids and TINs are used in practice, and a clear choice between them is not obvious as they both have pros and cons.

Visibility

Given a terrain model, two arbitrary points a and b are considered to be visible to each other if their *line-of-sight* ab (the line segment between a and b) lies entirely above the terrain (Figure 1a). The most studied visibility problem on terrains is the *viewshed*: Given a terrain and an arbitrary point v , the viewshed of v is the set of all points in the terrain that are visible from v (Figure 1b). In addition to viewsheds, a number of other visibility-related problems have been researched. The *cumulative viewshed* of a set of V of viewpoints is the part of the terrain that is visible to at least one viewpoint from V . The *visibility index* of a point v represents the size of the viewshed of v , where the size represents the number of grid points that are visible from v (on a grid), or the geometric size of the visibility map (on a TIN). On grid terrains one can further define the *total viewshed*: This is another grid, of the same size as the elevation grid, where the value at a grid point v represents the visibility index of v .

Efficiency and accuracy

In order to be useful in practice, algorithms that compute visibility need to be efficient (the time to compute the results is reasonable) and accurate (ideally, the computed results match the ground truth). It is obvious that the accuracy of the computed viewshed depends on the accuracy of

Figure 1 (a, b) Visualization of a grid digital elevation model (DEM) for Brunswick, ME, the United States. The viewshed of a point v at coordinates (100,100) from the upper left corner of the grid is shown in dark gray. (c) Two points on a terrain are visible to each other if the interior of their line-of-sight stays entirely above the terrain. Here (v,a) are visible but (v,b) are not. (d) A grid DEM and its associated matrix of elevation values. (e, f) To determine whether p is visible from v, the DEM needs to be interpolated along the line-of-sight vp. (e) In a stepped grid model, as used by Van Kreveld (1996), each grid point represents a square cell centered at that point. Cells that intersect vp are shown in gray. The elevation of these cells is considered to determine if p is visible. (f) In the grid-line model, the terrain is represented by connecting grid points with horizontal and vertical lines, and interpolating the elevation linearly inbetween points. Grid lines that intersect vp are shown in gray. The elevation of these points is considered to determine if p is visible.

the data: For example, a viewshed computed on a grid terrain at 1-km resolution is not going to be very realistic, no matter what the algorithm does. The second factor in the accuracy of the output is the algorithm itself: Given the same terrain model, various viewshed algorithms may obtain different viewsheds based on the models they use. An algorithm may introduce inaccuracy by

employing approximation to infer which points are visible without computing them explicitly, which overall makes the computation less accurate but more efficient. The interplay between accuracy and efficiency is important, and users that understand the models in which various visibility algorithms work are able to choose the right one for their particular application.

In recent years, with the advances of LiDAR technology, the accuracy of terrain data has gone up tremendously; terrain models at 2-m resolution are now common and consist of billions of points. Computing visibility on high-resolution data is very appealing in practice because of its accuracy; however, efficiency becomes the crucial issue. Many geographic information systems (GIS) offer modules to compute viewsheds and even total viewsheds. These algorithms tend to struggle when working on very large data and the computations can take many days or may not finish at all. This is one of the reasons that many researchers have worked on developing viewshed algorithms with improved efficiency. An algorithm's efficiency is characterized theoretically by the asymptotic complexity of its running time, which is described below. Theoretical running time analysis of algorithms aims to estimate how algorithms will behave in practice, and is crucial for understanding and comparing algorithms.

Algorithm running time analysis

The running time of an algorithm is modeled theoretically as the number of primitive “steps” executed in a generic computer where all instructions are assumed to take the same amount of time (the RAM model). In general, the time taken by an algorithm grows with the size of the input, so it is traditional to describe the running time as a function of the input size, n . The worst-case running time is the longest running time for any input of size n . When analyzing algorithms we are usually interested in the asymptotic efficiency of the worst-case running time, that is, how the running time increases with the size of the input, in the limit, as the size of the input increases. Asymptotic efficiency of the running time is usually expressed using $\Theta()$ notation. In short, a $\Theta()$ bound for the running time is a function that behaves asymptotically the same as the running time. For example, saying that the worst-case complexity of an algorithm is $\Theta(n)$ means that the worst-case running time grows as a linear function. We usually consider that one algorithm is more efficient than another if its worst-case running time has a lower asymptotic order of growth. This is not necessarily true in practice for small inputs (due to omitting constants and lower-order terms), but it is usually true for large n . Thus,

asymptotic analysis allows for a simple characterization of the algorithm's efficiency and also allows us to compare the relative performance of alternative algorithms; it is considered to be an excellent predictor of performance in practice.

Outline

The rest of this entry surveys known algorithmic results for computing viewsheds on the two terrain models that are being used in practice (TINs and grids), with emphasis on the computational complexity of their running time.

Viewsheds on TINs

Let T be a terrain represented by a TIN of n points. Recall that, given a point v , the viewshed of v is defined as the set of points of T that are visible from v . We refer to this as the *geometric* viewshed, to emphasize that it consists of all the points in the terrain that are visible from v and that we want the precise geometric shape of the viewshed. Put differently, for each triangle in the TIN, we want to find what part of it is visible from v . The viewshed of v is the union of all visible parts of all the triangles in the TIN.

An important issue to consider for a geometric viewshed is its size, that is, the number of vertices and edges on its boundary. The viewshed can intersect a triangle multiple times and a vertex of the viewshed is not necessarily a vertex in the TIN. It is known that in the worst case there may be $\Theta(n)$ triangles such that the boundary of the visible part of each of them consists of $\Theta(n)$ line segments, and thus a complete viewshed may have size $\Theta(n^2)$. A quadratic space complexity of the viewshed would make its computation unfeasible, especially on large TINs. Fortunately, in practice, the complexity of viewsheds seems to be close to linear. Some theoretical explanations are known. Most notably, it is known that the smoothed complexity of a viewshed is linear, based on certain assumptions on the shape of the terrain (De Berg, Haverkort, and Tsirgiannis 2010).

Several algorithms are known for computing geometric viewsheds on TINs. The algorithm with the best theoretical bounds on the running time is due to Katz, Overmars, and Sharir (1992) and runs in $O((n \alpha(n) + k) \lg n)$, where k is the size of

the viewshed and $\alpha()$ is the inverse Ackermann function. The algorithms introduce and exploit the concept of *horizon*: The horizon of a TIN terrain with respect to viewpoint v is a function $h(\theta)$ defined for any radial direction $\theta \in [0, 2\pi]$, such that $h(\theta)$ represents the minimum zenith angle which a ray from v with azimuth θ must have in order to be above the terrain. It has been shown that the horizon of a TIN of n points has complexity $H(n) = n\alpha(n)$.

Since the smoothed complexity of the viewshed is linear, algorithms that are sublinear in the worst case can be obtained only through approximation. One idea is to simplify the terrain to reduce its size and compute visibility on the smaller, simplified terrain. Another approach is to divide the area around the viewpoint into a number of slices, with each slice bounded by two rays from the viewpoint, and compute a one-dimensional viewshed along each ray; if the visibility map of the two rays bounding a slice is similar enough, the viewshed of the whole slice is constructed by interpolation between the bounding rays; otherwise the slice is subdivided into smaller ones. Both approaches were shown to give good results in practice.

In summary, computing geometric viewsheds on TINs has been thoroughly studied and several efficient algorithms are known. However, computing the exact geometric viewshed may not always be necessary (and some may argue that the shape of the viewshed inbetween the sample points is not accurate anyway). A “discrete” version of the viewshed may be defined as follows: the *vertices* of the TIN that are visible from v . That is, we are only interested in which sample points are visible and which ones are not. This is known to be a special instance of the *ray-shooting problem* which is the following: Given an arbitrary viewpoint v and a ray in the direction (θ, α) , find the first face of the terrain hit by the ray from v in the direction (θ, α) . The horizon tree by Cole and Sharir (1989) can be used to answer ray-shooting queries with respect to a fixed viewpoint in logarithmic time. It has size $O(n\alpha(n) \lg n)$ and can be built in the same bound. Given the horizon tree, determining which of the n vertices of the TIN are visible from v can be done in $O(n \lg n)$ time and $O(n \lg n)$ space.

Viewsheds on grids

Let T be a terrain represented by a grid of n points. Grids can be used with a variety of interpolation methods, such as linear, bilinear, or nearest-neighbor. Although viewsheds on grids could be defined in the same spirit as on TINs (exact geometry), the standard model on grids is a simplified, discrete one: The viewshed of v is the set of *all grid points* that are visible from v . As a consequence, the size of the viewshed is at most $O(n)$.

The standard approach for computing viewsheds on grids is the algorithm known as R3. The idea is the following: To determine whether a point p in the grid is visible from v , compute the intersections between the horizontal projection of the line-of-sight pv and the horizontal and vertical grid lines, and compute the elevation of the terrain at these intersection points by linear or bilinear interpolation (Figure 1c, d). If pv stays above all these points, then p is visible. R3 is considered to produce the “exact” viewshed (to the extent possible by the data); however, its running time of $O(n\sqrt{n})$ is too slow in practice. A different implementation of R3 that runs in $O(n \lg n)$ time is possible using the horizon tree; however, it uses superlinear space, which probably means it is mostly of theoretical interest.

A variety of algorithms have been proposed that are faster than R3 while approximating in some way the computed viewshed: Some algorithms consider only a subset of the $\Theta(n)$ lines-of-sight; others interpolate the line-of-sight only at a subset of the $O(\sqrt{n})$ intersection points with the grid lines; while others have some other way of determining in $O(1)$ time whether a point in the grid is visible. Examples are XDraw, R2, Backtrack, Van Kreveld’s radial sweep, and IO-centrifugal: R2 runs in overall $O(n)$ time, which makes it very appealing in practice. Several researchers report that it produces a good approximation of R3 that outweighs its loss in accuracy. Its main idea is to compute lines-of-sight only for the grid points on the boundary, and use nearest-neighbor to approximate the visibility of the interior grid points. The algorithm XDraw runs also in $O(n)$ time and is faster than R2, while being less accurate. A generalization of XDraw, described by Izraelevitz (2003), allows the user to

set a parameter k , which is the number of previous layers that are taken into account when computing the visibility of a grid point. The algorithm by Van Kreveld (1996) runs in $O(n \lg n)$ and computes the viewshed by rotating a ray around the viewpoint (Figure 1e, f). However, the viewsheds generated by this algorithm and R3 can be slightly different due to the different interpolations used.

Dealing with big data

A couple of approaches have been proposed for computing viewsheds on large, high-resolution terrains. The first approach is using the so-called I/O-efficient algorithms, that is, algorithms that optimize both the number of instructions and the data transfer between memory and disk. I/O-efficient algorithms are used in situations where the terrain is so large that it does not fit in the main memory of a computer and resides in virtual memory on disk. I/O-efficient versions of R3, Van Kreveld's radial sweep, R2, and XDraw are known; see, for example, TiledVS by Ferreira et al. (2012) and the algorithms by Fishman, Haverkort, and Toma (2009) and Haverkort, Toma, and Wei (2013). In practice, these algorithms scale up to terrains that are more than an order of magnitude larger than available memory, and can compute viewsheds on terrains as large as 28 GB in a couple of hours on machines with as little as 0.5 MB of memory.

Another approach for handling large data is high-performance computing and parallel algorithms. Recently, a number of authors have exploited the availability of multicore computers, super-computers, and graphics processing units (GPUs), and described parallel implementation of R3, R2, and Van Kreveld's algorithms. For example, Osterman, Benedicic, and Ritosa (2014) report an implementation of R2 that is faster than TiledVS, with a factor of 10 speedup using GPUs, when running on datasets up to 180 GB. Although these algorithms do not provide a theoretical analysis of their performance and it is not clear how results will carry over to other platforms, they are a promising first step.

Conclusion and challenges

A variety of algorithms have been proposed for the computation of viewsheds on both grid and TIN terrains. Computing the viewshed with the full accuracy allowed by the data is possible, but may be too slow in practice. Many algorithms exist that introduce approximation in the computation, but are faster. A careful assessment of the accuracy/quality of the viewsheds computed by the various algorithms remains to be carried out.

While there is a large body of work on computing viewsheds efficiently, very little is known about computing cumulative viewsheds and total viewsheds. For the total viewshed, the best algorithm seems to be the straightforward one: Compute the viewshed repeatedly. This will take at least quadratic time and is only feasible on very small grids. Developing improved bounds for these problems remains open.

Virtual Reality Modeling

MAURIZIO FORTE

Duke University, USA

VRM (virtual reality modeling) embraces all the real-time applications in archaeology dealing with virtual reality (VR), 3D modeling, data capturing and data archiving (i.e., 3D repositories, online archives). VRM redefines the digital workflow from fieldwork to the laboratory post-processing and real-time visualization. In fact, almost all the datasets produced during fieldwork activities are in digital format, and they actually migrate from one platform to another, but always in digital domains. In other words, most of them can easily be implemented for virtual reality applications.

Virtual reality involves modeling and simulation technologies for human interaction with three-dimensional visual content at different levels of immersivity and in a multisensory manner. The user interface can include gloves, goggles, wearable headsets, controllers, or other kinds of body interaction and simulation. The performance is typically in real time (at least 30–60 frames per second) and the modality of interaction is designed by software and graphic interface (GUI, graphical user interface). Although virtual reality technologies were invented in the 1960s, the most effective “reinvention” belongs to the game industry and the high graphic performances of personal computers. In the twenty-first century, virtual reality can be considered a revolutionary technology mostly because of the massive production of game technologies and inexpensive digital tools and devices and the introduction of personal immersive systems, such as Gear VR, augmented reality devices Oculus Rift, Google glasses, HoloLens, and the like.

The passage from fully immersive systems to massive virtual reality systems has completely revolutionized the use of VRM in archaeology, museums and digital archives. Online and open source platforms such as Sketchfab (a community of over half a million content providers) and

3D HOP (<http://vcg.isti.cnr.it/3dhop/>) show the relevance of Internet archives and repositories for the digital preservation, usability and dissemination of 3D models. The portability of models, from on-site data recording to immersive environments and/or online platforms, can possibly guarantee long-term digital preservation and adequate cultural transmission. They also improve the usability of models and the accuracy of interpretation for a large audience.

The definition of *model* is still debatable: virtual reality requires typically geometric meshed models, equipped with textures and color information. But in a broader sense, a model can be also a simulation, a mathematical unit or a process. VRM deals typically with geometric (meshed) models and point clouds, by on-site (empirical) data recording or by 3D graphic virtual reconstructions. The integration of empirical data collection and digital reconstruction/simulation deeply influences the interpretation and the creation of an inferential model.

A pioneering use of VRM in archaeology dates back to the 1990s, when Mark Pesce co-invented virtual reality modeling software (VRML, Virtual Reality Modeling Language) (Pesce 1995; Forte and Siliotti 1997), with the intent to display 3D (three-dimensional) models and scenes on the Web by real-time interaction. In the first book on virtual archaeology (Forte and Siliotti 1997), the chief editor (Forte) discussed the pioneering potential of VRML in relation to virtual archaeological reconstructions.

At the dawn of VRM, in the early 1990s, no personal computer was able to generate full real-time interaction (30–60 fps) with complex archaeological models or 3D scenes. This was the era of virtual archaeology (Barceló, Forte, and Sanders, 2000; Forte 2010; Forte and Campana 2017) where the models were generated by computer graphic rendering and not by real-time engines. The output related to rendered images and computer graphic animations, but with no interaction with models. In that context, the VRML had the utopian goal to transform Internet navigation into a 3D cyber-world. For archaeology, the initial

DOI: 10.1002/9781119188230.saseas0596

pivotal goal was to transform static 3D models in interactive scenes, by merging empirical datasets with virtual reconstructions, via VRML. This preliminary software development did not succeed and the VRML did not become a standard. Such a lack of 3D standards is still an issue for online archives and 3D repositories.

In the last two decades, the amount of digital models and datasets in archaeology grew exponentially; this was due to the massive use of laser scanners, digital photogrammetry, photomodeling and remote sensing technologies (UAVs, lidar, micro-scale data recording). This proliferation of models and datasets was not guided by an adequate policy of data archiving or an open-access strategy.

The technologies of data capturing involve different categories of sensors, devices and tools: laser scanners, drones, lidar, and digital photogrammetry, for example. All the models are created by other digital datasets and not by analogue data. The new generation of VRM (real time, immersive, interactive) is associated with the revolutionary approach designed by cyberarchaeology.

The definition of cyberarchaeology was formally introduced and discussed for the first time in a workshop at the TAG (Theoretical Archaeology Group) Conference in Stanford (May 1–3, 2009) within the conference *Diversifying Participation: Digital Media and Learning*, and in a second workshop on Virtual Collaborative Environments for Cultural Heritage (February 18–20, 2010 in San Diego, La Jolla). The workshop organized for TAG was aimed at analyzing the epistemology of cyberarchaeology in relation to the research topics of the conference. The workshop in San Diego was mainly focused on collaborative virtual environments, virtual models and simulation studies. Finally, in a scientific monograph published in 2010 (Forte 2010), cyberarchaeology was accepted as a discipline with specific research perspectives. In short, cyberarchaeology is the science of multimodal 3D simulation/interaction of archaeological datasets in different domains. The massive use of 3D digital technologies in archaeology, in fact, is identifiable in new digital workflows and real-time simulation of archaeological datasets. Cyberarchaeology deals also with “big data”, like many other scientific fields of the digital era.

In fact, it is possible to estimate that around 2.5 quintillion bytes of data are generated every day; 80 percent of them were created in the last two years. Archaeology, on a very small scale, is part of this revolutionary social and technological change. The outcome of this revolution is a hyperdescriptive reality, where the impact of informational growth requires different inferential and epistemological models. The impact of this revolution has still to be studied in detail and with a new “digital metrics”.

This digital migration of data and models in such diverse domains creates unexpected results and more advanced knowledge. Study of the code is mandatory for re-analyzing the interpretation process in the light of a cybernetic perspective: the feedback created by different users operating in the same environment/ecosystem generates further feedback and unexpected interconnections. In the last few years, the implementation of 3D online platforms such as Sketchfab, Tdar and 3D Hop launched a new era of 3D browsing, where many users are also content providers or co-creators. In addition to the pure visualization, several tools are nowadays focused on simulation, annotation, and collaborative work.

From this point of view, the core of the process is not in the virtual model itself, but in the mutual relations produced by interaction/embodiment/enaction with the model. The study of VRM in cyberarchaeology is focused on these relations and on the capacity to generate new research questions during the simulation process. The interpretation of the model depends on the complexity of interaction and the level of embodiment of the user. Recent studies in neuroscience show clearly that the embodied simulation is a multimodal process (body–mind) able to discretize in affordances and spatial relations (Gibson 1979) our experience with/between objects and environment.

All perceivable information in the environment comes from a perceptual–motor interaction. The acquisition of data from the environment can be identified in the circularity between action and experience and between action and knowledge. This process can be seen at the intersection between empiricism and simulation: empiricism by developing tools for data capture and autoptic evaluation in the field; simulation in relation to data processing and modeling

in labs and virtual environments. Along with the functionality of VR to enable unique ways to integrate spatial maps and VR renderings through a series of virtual models, a second functionality deals with the ability to find relationality between many different digital media artifacts. Therefore, the archaeological interpretation is characterized by multivocality, collaborative work, networking, new digital media and open digital narratives; it is a fluid and open process.

VR interactions

Virtual reality systems are able to provide a three-dimensional embodiment and a high level of immersive engagement and interaction in relation to the software interface and models design. VRM requires different levels of immersivity and interaction, based on the modality of engagement between users, models, and virtual environments. For example, immersive 3D applications are aimed at simulating a sense of presence inside the application and, because of the spatial embodiment, to stimulate a more participatory involvement of the user. VRM applications can be classified in terms of level of immersion and interaction. For example, gestures, visualization, and multisensory involvement influence the user's feedback. Typically, these applications provide "walkthrough" or "flythrough" actions within the virtual environment, so that the user is involved as an avatar or in the first person. The role of the user is fully active and they are able to control the environmental conditions within the digital simulation as "human avatar".

One of the first experiments involving VRM in real time on personal computers was the reconstruction of the Paleolithic caves of Lascaux, made by Benjamin Britton in the 1990s, by Head Mounted Display (HMD) interaction (Forte and Siliotti 1997). Later, the project "Virtual Petra" hosted in the ArchCAVE at Brown University (Shape Lab; Joukowsky 2002) was one of the first immersive virtual reconstructions of a monument in relation to archaeological artifacts and strata.

Pivotal and early applications in virtual theaters were the NUME Project (CINECA, Bologna) and Rome Reborn (UCLA, Los Angeles, University of Virginia), both started in the late 1990s. NUME (New Electronic Museum of

the city of Bologna) was aimed at the historical reconstruction of Bologna, starting with the twelfth century CE. Rome Reborn (Kimberly et al. 2010) was focused on the virtual reconstruction of Rome around 320 CE.

In the twenty-first century, the use of immersive applications has involved museums, cultural and research institutions with the scope to involve a higher number of users in virtual environments, thanks also to a more extended use of personal computers. Major attention has been paid to applications involving a higher number of simultaneous users, and to increase the space of immersivity in archaeology. For example, the Virtual Flaminia Project (Forte et al. 2006) developed a collaborative application for multiple users with the scope to award navigation and interaction by digital teamwork and exploration. In the "Place Hampi" virtual museum (Kenderdine 2010), the interaction involves multiple users in a large virtual room.

Additional experiments with collaborative VRM involved teleimmersive technologies (Forte and Kurillo 2010). In 2010, a successful experiment with teleimmersion was accomplished by UC Merced and UC Berkeley: users from different university campuses were operating in the same cyberspace and sharing the same 3D data. The primary goal of such collaborative frameworks is to facilitate immersive real-time interaction among different 3D datasets and models. The main case study was the reconstruction of the excavation process of the Neolithic site of Catalhuyuk (Turkey). In this case, all the layers recorded by laser scanner, artifacts, GIS layers and databases were shared in the 3D space.

Micro-scale applications of VRM concern the virtual visualization and simulation of archaeological excavations, by layers, units, finds, and contexts. This is due mainly to the intensive use of digital photogrammetry (based on shape from motion and computer vision), 3D laser scanning, lidar, and remote sensing technologies (Forte and Campana 2017).

VRM in a time span of 25 years has revolutionized the approach to archaeological data, from fieldwork to digital simulation and VR reconstruction. The core question is always the representation of the past, its digital preservation, and its transmission to future generations. It is a broad research field since it involves the

use of digital technologies in the field as well as virtual reconstructions for real-time digital environments (HMD, augmented reality, desktop, immersive) or portable devices, such as smartphones, tablets, and the like.

The dissemination of apps for different devices, from immersive VR to smartphones and augmented reality, opens up new perspectives for VRM. For example, future digital publications in archaeology could be based on augmented or mixed reality tools and linked to public online repositories.

VRM datasets constitute the libraries of the future where the interpretation process is constructed during the virtual performance, and potentially every interaction can produce new knowledge and a different kind of learning.

Visibility Modeling

MARCOS LLOBERA

University of Washington, Seattle, USA

Visibility has always played a role in archaeological investigations. It can be found, explicitly or implicitly, in discussions on political power, territory and control, symbolism, social space, and so on. The possibility of modeling visibility has only been possible since the development of geographical information systems (GIS) and, to a lesser degree, other software platforms and paradigms such as space syntax and virtual reality. In the case of GIS, visibility modeling is achieved primarily through the repeated calculation, and combination, of *viewsheds*. A viewshed is best interpreted as a regular sample of the area of “potential visibility” around a point given on the topography (represented by a digital elevation model or DEM). Viewsheds refer to the visibility of a surface (mostly represented by a raster) and not to any target on it. By “potential visibility,” we refer to the surface area that remains unobstructed by topography. Locations (cells in a raster) that are visible from a viewpoint are usually encoded with a value of 1, those that are not visible with a value of 0. In this sense, viewsheds are better expressions of what remains hidden than what is visible. Early discussion of several of the limitations surrounding the use of viewsheds may be found in Wheatley and Gillings (2000).

Archaeologists have modeled visibility within a wide range of interpretative contexts, covering many archaeological periods and site types. Yet the nature of the questions has remained fairly narrow. For the most part, visibility has been approached as part of investigating the locational preferences of people in the past. Interest has been in assessing whether visibility was a factor when choosing the location of a particular site or monument. Many of the methods that archaeologists have used to study this topic rely on some Monte Carlo simulation variant where observed visibility patterns are compared against similar

patterns derived from random points (sometimes the samples are stratified, or controlled in some manner). The nature of the comparison varies: sometimes it will be based on whether existing sites have the same level of intervisibility as those generated randomly, whether local perturbations in site locations change significantly the size of visible areas associated with each site, or whether the content of the views are similar or not. Similarly, archaeologists have used certain methods to identify and describe the significance of certain natural features such as particular peaks or horizon shapes as seen from sites. Until recently, and despite the locational undertones, the majority of investigations have approached the study of visibility in isolation without considering how visibility may have interacted with other confounding factors. This is the subject of a paper by Eve and Crema (2014), who used point-based spatial statistical techniques to explore how the locational choices of several Bronze Age houses in the Leskernick Hill area (Cornwall, UK) may have resulted from the combination of visual and nonvisual factors as well as spatial interaction among pre-existing sites. To this day, however, the most common question that archaeologists continue to explore is whether sites are intervisible among themselves. This was first considered by Wheatley (1995) in his study of visibility patterns among monuments located on the Salisbury Plain and the Avebury region in the UK. This approach was further improved and extended by Fisher and colleagues (1997) when investigating the location of a set of Bronze Age cairns on the island of Mull (Scotland). Both studies relied on the calculation of *cumulative viewsheds*, raster layers generated by the repetitive “addition” of viewsheds where each location, or cell, contains the number of times that location is visible from one or more viewpoints. The popularity of this type of analysis has greatly benefited from the creation of specialized GIS toolkits such as those found in GRASS, and continues to be enhanced through the use of complex statistical methods as illustrated by Brughmans, Keay, and Earl (2014). In this work, the authors use a particular

DOI: 10.1002/9781119188230.saseas0598

approach in network analysis, exponential random graphs models, to explore how the pattern of intervisibility among Iron Age and Roman settlements in southern Spain may have resulted from the repeated application of a set of smaller-scale (inter-)visibility goals.

In the course of their investigations, archaeologists have also sought to extend the standard output of the viewshed routine as a way to include other visual information or derive additional visual parameters. Thus, archaeologists have combined distance and directional information with the standard output of viewshed in order to further characterize viewsheds (how evenly distributed they are) and separate visible areas into distance bands (Wheatley and Gillings 2000). Similarly, the calculation of visual angles has allowed them to provide a (theoretical) measure of the level, or clarity, of cultural features or to distinguish visual planes, that is, foreground, middleground, and background (e.g., Llobera 2007). These studies are significant because they try to incorporate, within the limitations of the standard viewshed calculation, objects and/or a sense of scale. However, modeling visual parameters aimed at exploring more subtle qualities that refer to the appearance (what does it look like?) of the sites or monuments have been less forthcoming. Some early attempts may be found in the works of Lake and Woodman (2003). More recently, Llobera (2015) calculated angle of elevation and angle of incidence to investigate the appearance of Mamoas (round barrows) when viewed along the ridgeline on the Sierra de Barbanza (NW Spain).

It must be said that the majority of the studies mentioned above approach visibility by focusing on the relationship between points in isolation, and ultimately, resolving a simple question: whether a set of particular points (often standing for archaeological remains) are visible (not obstructed) from another set of points or from each other. Through the concept of visualscape, Llobera (2003) attempted to point out the limitations of this pointillistic view, and draw attention to the possibilities of retrieving structural properties of visual space. By this view, *cumulative* and *total viewsheds* (Wheatley 1995; Llobera 2003) are to be interpreted as particular expressions of such structures that might be studied in their own right. Similarly, the great majority of modeling

efforts have sought to produce static snapshots of the visibility patterns for specific time periods. So far, limited work has gone towards understanding the process by which these visual patterns emerged and the significance of such a process for landscapes (see Llobera 2007; Brughmans et al. 2014, for some hints and early explorations).

Finally, it is important to acknowledge some of the more subtle implications that surround current GIS-based visibility models. A viewshed is the result of repeatedly connecting two points with a line (of sight, or LoS) and checking whether this is interrupted by the intervening topography. Using LoS as a way to explore (potential) visibility has both advantages and disadvantages. The viewshed routine, currently, allows us to generate quite easily the different views from and towards a point (sometimes referred to as *projective* and *reflective* viewsheds), which may be used to model paths with different visual qualities. With some notable exceptions, within the current viewshed paradigm, modeling efforts are somewhat constrained to representing features as combinations of points which might, without careful consideration, have unintended consequences. Despite criticisms (see above), visibility modeling represents a vibrant area of research which is likely to grow in future years.

Visualization of Ground-Penetrating Radar Data

ASHELY GREEN

Bournemouth University, UK

Ground-penetrating radar (GPR) is an active electromagnetic technique which delineates changes in the dielectric, conductivity, and overall electromagnetic properties of subsurface materials. GPR systems emit electromagnetic pulses of a central frequency into the subsurface. The electromagnetic signal is reflected or refracted upon converging with variations in the subsurface material, the amplitudes of which are presented almost immediately during survey. Three-dimensional (3D) renderings can be “sliced” to specific depths that are estimated by calculating the relative velocity of the subsurface material and two-way travel time to be exported as raster images or 3D animations. Recent work has further explored the integration of GPR data, other geophysical data, and remote sensing data with digital terrain models and light detection and ranging (LiDAR) data.

History of visualizing GPR data

The first application of what could be considered a crude GPR system was used to measure the thickness of ice on glaciers in 1929 Austria. The use of GPR expanded to use in geology and utility surveys in the 1970s, by which time the United States National Aeronautics and Space Administration (NASA) had built a GPR system to send to the moon. From the mid-1970s to the 1990s, the use of GPR systems, and geophysical survey in general, in archaeological science grew immensely. The 1980s saw a major growth in the use of GPR systems for landscape surveys, particularly in Japan (Conyers 2013). However,

at this time, processing reflection profiles was problematic as they were printed on paper. In 1982, the first datasets were corrected for relative soil velocities. Moving into the 1990s, major improvements to GPR survey and data processing came with technological advances, particularly in computer hardware and ad hoc processing software. It became much easier to process data as they were stored on digital files during survey. After 1993, the field also saw the first use of amplitude slice maps, computer-simulated two-dimensional (2D) models, and 3D reconstructions with these computing improvements (Conyers 2013).

In its initial stages, commercial GPR data were collected along coarsely spaced traverses in analog and digitized as 8-bit, whereby interpretation and, when possible, processing were quite time consuming (Conyers 2012, 48). Reflection profiles were printed on paper and from these profiles responses were hand-drawn as crude contour maps of anomalies (Conyers 2012, 49). Today, digital data are collected and presented almost immediately in the field as 16- or 32-bit data, and 0.5 ha of gridded data can be rendered for interpretation in less than 30 minutes.

Image processing and rendering

Once the radargrams have been processed to reduce noise and create spatially accurate data, they can be presented as radargrams, slice maps, 3D animations, and isosurface models, and overlain with other forms of geophysical and remote sensing data. In 3D rendering, the space between radargrams is interpolated; as such, the first step to producing high-quality raster outputs is to collect high-resolution data in the field (Leckebusch 2003). The primary methods of interpolating between data are kriging and inverse distance. Kriging solves an inverse covariance matrix to abate the error between data and interpolated points, often producing superior results (Goodman and Piro 2013).

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

© 2018 John Wiley & Sons, Inc. Published 2018 by John Wiley & Sons, Inc.

DOI: 10.1002/9781119188230.saseas0603

Inverse distance interpolation is faster and more mathematically simplistic, where nearby points are averaged to estimate an interpolated point, based on the distance to the interpolated point. Weighting is proportional to the inverse square of the distance between a known point and the estimated point (Goodman and Piro 2013). Once grids are interpolated there are two options: If data were collected in zig-zag or global positioning system (GPS)-tracked mode, grids will need destaggering; if data were collected over multiple days or vastly different geologies, grids may require mosaic correction to reduce the effects of variable moisture content, weather conditions, equipment settings, and/or geological contrasts across a site (Conyers 2013).

Post-processing data

As with other geophysical techniques, prior to rendering, datasets must be processed. Radargrams and depth profiles are comprised of pulses transmitted by the GPR antenna and the response from the ground surface, subsurface material, and GPR signal noise. In order to analyze only the responses from the subsurface material, extraneous data can be processed and rectified. Though some GPR systems record and present minimally processed gained data in the field, filtering is necessary to view later-arriving reflections, determine and correct for relative soil velocity, and remove noise. The processed signals are then compiled to be rendered as raster images, vector data, and animations. The frequency, amplitude, velocity, and phasing of reflection waves are particularly important to processing and interpreting GPR data (see Table 1). Importantly, however, it is vital not to overprocess data or arbitrarily apply filters to datasets as this could produce distorted, uninterpretable data.

Radargrams or *depth profiles* are 2D representations of an individual traverse (Figure 1a). As such, these files are quite easy to view in basic software with little processing. Nevertheless, corrections for gain, migration, and direct current (DC) drift are still necessary. Profiles are particularly useful for viewing hyperbolic reflections during the interpretation stage of a survey, but alone are not a viable method to

visualize entire sites as they are not a complete “picture” of the subsurface nature of an area, rather just an individual traverse. Therefore, when interpreting results it is recommended that profiles be viewed in conjunction with slice maps, as XY trace plots are viewed alongside grayscale plots when interpreting other geophysical data.

Slice maps or *amplitude maps* are sections of gridded data at a specified depth below the ground surface, called time slices (Figure 1b), that demonstrate the scale and spatial distribution of responses (defined herein as a change in amplitude) in a given area. Rendering data this way allows for a plane view of any responses of interest and provides the end user with 3D data. Maps can be presented as a single slice or a series of stacked slices that demonstrate the change in an anomaly as depth increases (Conyers 2016, 13, 119). Slice maps are the most common method of visualizing GPR data as they provide a complete view of a given area. The slice thickness and overlap are set by the user, which allows for targeting specific depths. Once time slices have been created, they can be interpolated and transformed into an animation. Animations allow the end user to visualize the changes in the subsurface matrix in real-time, which aids in identifying subtle changes and patterns.

Modeling and simulation has developed since the 1990s when Dean Goodman created software to simulate archaeological features in GPR datasets based on known or expected electromagnetic and morphological properties of buried objects (Conyers 2016). By inputting parameters such as dielectric permittivity, conductivity, and morphology into the software, 2D reflection profiles are created from artificial simulated wave paths (Conyers 2016, 41). Simulated models are useful in demonstrating how a buried object may present differently within a range of geological background materials (Conyers 2012, 50). 3D models can also be used to show the volumes and morphology of anomalies of interest. It is important to note that the accuracy of simulated models is entirely dependent on the quality of the known values used to create the model.

Isosurface rendering generates 3D surfaces which represent points in 3D space measuring a

Table 1 Common usage and effects of GPR signal processes (Goodman and Piro 2013)

<i>Process</i>	<i>Purpose</i>	<i>Effect</i>
Resampling	Correct variation in the number of scans per user-set navigation marker and create accurate spatial density information	Sets the number of scans per user-set distance unit to a constant by interpolating between scans to create additional scans
Gain	Visualize later-arriving, weakly visible attenuated reflections	Intensity, or amplitude, of radar reflections increases
Migration	Correct for signal spread and subsurface velocity distortion, particularly over variable terrain which causes signal diffraction, skews two-way travel time, and distorts morphology of responses Estimate relative soil velocity based on the principle that broad hyperbolic reflections indicate fast velocity and narrow hyperbolic reflections indicate slow velocity	Removes extraneous hyperbolae by determining the “point source” of reflections by averaging the reflection energy of each hyperbola in the dataset. In Kirchhoff migration the angle of incidence and depth of reflective feature undergo a correction based on a tacit velocity profile, reducing positional errors and collapsing hyperbolae
Hilbert transform	Visualize weak reflections by considering absolute value of data and connecting peak responses	Fourier transform (FT) is run on radar pulses, negative frequencies are shifted 90°, and then an inverse FT is run, creating a signal in the positive domain and represents the envelope of recorded pulse
Background removal	Filter out horizontal banding caused by signal noise in order to view slight reflections near the surface	Algorithms determine average waveform across a radargram and subtract this value from all in the dataset
Bandpass filter	Remove noise resulting from post-processing gain and “ringing” or signal noise from antenna	Utilizes one-dimensional Fast Fourier Transforms (FFTs) to remove noise from radargrams. FFTs convert radar pulses/signals into their spectral components (amplitude and phase at each detected frequency). Radar waves can be low-pass filtered or high-pass filtered
Spectral whitening	Remove noise resulting from post-processing gain and “ringing” or signal noise from antenna	Normalizes real and imaginary spectral amplitudes by converting data utilizing FFTs and setting the magnitude of spectral frequencies to 1
Deconvolution	Minimize negative effects of previous processes	Spectral division deconvolution utilizes FFTs to convert data to the frequency domain, remove the antenna’s impulse frequency by dividing the frequency response of the radargram by the frequency response of the impulse, and revert data back to the time domain Cepstrum deconvolution normalizes the data using a logarithmic scale. Predictive deconvolution utilizes the preceding signal to predict the succeeding value in the radar scan

Figure 1 Selection of rendering options. (a) Depth profile; (b) time slices; (c) isosurface.

constant value, which in the case of GPR is often the amplitude of reflected waves (Figure 1c). Visualizing data in this orientation is particularly useful for extracting responses of interest. As isosurfaces can be rotated and coded to show all aspects of an anomaly, they are a key tool in representing and understanding the full extent of buried objects. Isosurfaces can be imported into computer-aided design (CAD) programs to be georeferenced and combined with geographical information system (GIS) data and other forms of geophysical data.

Data fusion and *multicomponent integration* allow the end user to merge data from a range of geophysical techniques, remote sensing, and spatial datasets. As most geophysical techniques measure one property, combining data to create a multicomponent 3D dataset can improve accuracy and confidence in interpretations. This is key when visualizing and interpreting GPR data which often contain a large number of anomalous responses. Integrating datasets highlights responses of archaeological potential hidden among extraneous responses. Kvamme (2007) discusses the merits of various integration approaches, such as mathematical and statistical operatives (e.g., Boolean union, Boolean intersection, thresholded binary sum, principal components analysis, k-means cluster analysis, binary logistic regression), computer graphics solutions (e.g., 2D overlays, red, green, blue (RGB) color composites), and vectorized interpretative integration.

Interpreting GPR data from an archaeological perspective

GPR data can be presented in RGB value color scales or grayscale to aid in the interpretation of data (Figure 2a,b). Choosing a color scale is particularly important in presenting GPR data, in part because of the wide range of responses and slight variations in measured amplitude often encountered in datasets (Conyers 2012). Applying a color scale based on the standard deviation from the mean is far more accurate than assigning the color scale based on the range of values in the dataset (Goodman and Piro 2013). Plotting in color helps to visualize weaker responses as there

are more color assignments available. Also, they produce contrasts in the dataset which might not exist in reality as a result of color strength, thus the need for grayscale plots. Grayscale data are plotted with equal weighting on all reflections, but often cause weaker reflections to become obscured in datasets with a large range (Goodman and Piro 2013).

The color scales in a given plot coarsely correspond to numerical values indicating the amplitude of a response. Sliced data can be plotted in relative normalization or absolute (Figure 2c,d). In relative normalization, colors are assigned relative to the strongest response in that given slice. This shows weakly visible responses but will plot the same response differently in multiple time slices. Plotting in absolute is similar to clipping magnetic or resistivity data. Responses are colorized with respect to the maximum and minimum values of the dataset, which produces a more consistent scale but tends to remove weakly visible responses. Best practice is always to view the data in both aspects to be able to accurately interpret the origin of any anomalous responses.

Interpreting GPR data is often considered more complex than other techniques (Conyers 2012; Goodman and Piro 2013), partially due to the nuances of processing the data but also because of the sheer number of objects GPR could possibly detect. It is important in interpretation to not only look for “anomalies” but to view the entire “picture,” as areas of no or low reflection can be as telling as stark high-amplitude responses. While many advances in GPR data collection and processing have been made since the 1990s, further enquiry is necessary to fully grasp its applications to archaeological investigations. Particularly, the effects of traverse and sampling interval size on data quality and the ease and confidence of data interpretation requires exhaustive analysis. With growing popularity in remote sensing, automatic feature detection and extraction can also be useful in GPR surveys provided a comprehensive characterization of archaeological materials is conducted. However, these methods with respect to archaeo-geophysical datasets are still in their infancy as training systems and datasets are still being compiled for machine learning methods.

Visualization of Magnetometer Data

ROBERT FRY

University of Reading, UK

Magnetic survey is one of the most efficient and useful geophysical survey techniques. Due to the rapid data acquisition that is possible, large areas of land can be covered relatively quickly, at a high spatial sampling resolution. Due to the speed and detection success rate, magnetic survey is currently the most relied-upon archaeological geophysics surveying technique, and is consistently seen as the workhorse of archaeological geophysics.

Effective and efficient computer processing of magnetometer data is essential as landscape cover, survey speed and efficiency, and therefore raw data, increase every year. Appropriate data processing and visualization is as important as the collection of data in the field, as it transforms raw data into information which can be effectively interpreted. The aim of the processing and subsequent visualization is thus to provide both the specialist and the non-specialist with a dataset that can inform decision-making and risk management in a sensible and accurate way.

Data collected in the field can, in its raw state, contain various sources of interference, noise and errors, which can detract from the dataset and obscure anomalies of archaeological interest from identification. In the broadest of terms, such sources of noise can be classified as “spikes, stripes and zigzag effects” (Ciminale and Loddo 2001, 239). The treatment and processing of magnetic data is therefore designed to remove such faults within the data, while enhancing anomalies of particular interest. Data processing is usually conducted on specialist or customized software programs, of which a variety exist with broadly similar overall statistical and algorithmic functionality.

Magnetometers (see MAGNETOMETRY) are passive instruments and will record any detectable

ambient magnetic field. The Earth’s magnetic field is extremely strong compared with anomalies of archaeological interest, and to compound the issue, the Earth’s magnetic field also fluctuates diurnally. Therefore data collected within the field will sometimes need to be pre-processed before further visualization techniques can be applied. In the case of magnetometers set up in variometer or single sensor configurations, for example, the diurnal variation of magnetic field strength will need to be accounted for. For other magnetometers where a fixed configuration is always set to a gradiometer, the Earth’s (as well as local) ambient magnetic field is usually removed from the readings at the survey setup, known colloquially as a zero or balancing point. In this instance, no further pre-processing is usually necessary.

Key processing routines

Data are downloaded from the instrument onto customized software packages via a cable, or more recently, passed from instrument to computer via a data-stick or wirelessly. The data streamed out of the instrument are usually in the format of a series of values (in nano-Tesla, nT) that can be viewed within a simple text editor. The format of the data contained within downloaded files will depend upon both the instrument and software used. When data are first entered into a processing package, the individual data-files may need to be mosaicked so that they are positioned in the correct order for the entire survey to display correctly (if surveyed in a gridded mode). If the data have been collected incorporating satellite positioning, then the raw data will be automatically positioned, with real-world coordinates attributed to each data value. The necessary data processing for magnetic data can vary from site to site, and various methods of enhancing or suppressing the data in specific ways will depend upon the site itself as well as the rationale and aims of the survey. The processing algorithms within the software are objective, mathematical, raster-processing functions, but the way they are used and manipulated for data visualization

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

is a subjective task for which the geophysicist is responsible. The following outlines a generic, basic processing procedure which would remove the most common sources of noise, and help to enhance anomalies of archaeological interest.

Magnetic data are usually “clipped” to diminish the influence of large, strongly enhanced (and reduced) anomalies within the dataset that may not be of any archaeological significance (such as field boundary fences or utility pipes). Usually a statistical model of the data is used to influence the clipping limits of the data, which may be set to a number of standard deviations of the dataset’s mean, or can be set to specific threshold values. Data with a low standard deviation but a large data range may require clipping, for example, as the majority of the archaeologically important data are almost always within one or two standard deviations of the dataset’s mean. Removing or suppressing large outliers within the data will also mean that they have less influence over more subtle statistical algorithms within the later processing stream.

Further visual improvements of magnetic data may include the suppression of both “drift” of the magnetometer and any heading errors introduced into the survey by the surveyor or sensors. These errors can be seen within the data as striping along the direction of traverse within the shade plot, as the background level of the data increases and reduces for each direction change. The background level for magnetometer data should be at 0 nT (when the Earth’s magnetic field is removed) and, as every magnetic anomaly will have an equal positive and negative field, the mean value of the entire dataset, and hence each traverse, should also be 0 nT. By using a process sometimes dubbed “zero mean traverse” or “de-stripe,” the background level over a whole traverse is adjusted down to the desired value of 0 nT. This greatly improves the quality of the data, and eliminates striping from the dataset.

Spikes are extreme readings or outliers within the dataset that may be caused by instrumental malfunction, or more likely by the presence within the soil of ferrous objects or high susceptibility debris, usually, but not exclusively, modern in origin. A de-spike function within most processing software will remove these strongly enhanced/reduced dipole anomalies

in the data caused by such point sources, and replace the offending data point with the median or mean of the data surrounding it. De-spiking of the dataset will therefore help to eradicate the distracting dipole point anomalies and improve the overall visualization of the data. Not all anomalies that look like spikes are necessarily non-archaeological in nature, so caution needs to be applied when using such functions.

Surveys walked without satellite positioning, and thus by a reliance on consistent walking speed, can suffer from a defect known as “stagger”. This is especially common for surveys walked in a zig-zag mode, usually by inexperienced or tiring surveyors, or when a significant topographical slope within the survey area affects the walking speed in one or both directions. If the walking speed has altered significantly between traverses, the resultant data will look extremely muddled, and be difficult to interpret. Such errors in data can make linear features appear disjointed or “like a zipper” in appearance (Aspinall, Gaffney, and Schmidt 2008, 124). A de-stagger function can shift traverses individually by a certain number of data points so that such archaeological anomalies line up correctly. It is important to make sure that staggering in the field is kept to a minimum, as shifting a traverse one way by a single data point will delete a data point from the end of the traverse, and create a false data point at the beginning. Excessive de-staggering of data can result in large areas of false data being created at grid edges, which both hinders interpretation and makes the dataset look amateurish.

Further visual improvements can be made to a magnetic dataset to increase the general appearance, and smooth out certain aspects of the data. Filters, such as a low-pass or median filter, are sometimes used to iron out small-scale, high frequency anomalies that may still exist. These generally work as a moving window algorithm over the dataset. Such windows will calculate an ideal reference value for the center of the window and replace the current center value if it is beyond a certain threshold. The data can also be interpolated, which is a process of falsely increasing the spatial resolution of the data so that blocky features become more rounded and natural. Both of these functions, if used well, can enhance the visualization of the data dramatically,

but the geophysicist must be careful to not lose subtle anomalies of archaeological importance by over-smoothing the dataset.

Visualization of processed data

The visualization of processed magnetic data has evolved at pace over the last half-century, as computing power and software capability has increased. Before computers could be used to visualize and digitize magnetometer data, manually drawn trace plots were utilized. This process, however, became ultimately “tedious and expensive,” and was eventually supplanted by digitizers (Clark 1996, 133). Another method of visualization, known as dot density plots due to the procedure of shading different data values, was first used by Scollar and Kruckeberg (1966) and became an effective computer visualization tool. With further advances in software, and on-screen and printing resolution, shade plots became the preferred method, providing an easy-to-interpret, map-like overview of the dataset, in which anomalies of archaeological interest could be identified through their form, magnitude, and size. Usually, magnetic data in a shade plot are presented in a linear grayscale, although conventions on color scales vary, and color can be used to highlight particular statistically enhanced or reduced magnetic anomalies of interest. Computerized trace plots are sometimes still used in geophysical reports and publication, and allow the viewer to assess the nature of the data in more detail. A further advance to some survey systems, accentuating the need for fast data processing, has been the development of processing algorithms that remove errors automatically (Eder-Hinterleitner, Neubauer, and Melichar 1996). Such has been the development over the last 20 years that real-time automated processing of magnetometer data over a 4G/wireless link is now a reality.

Once data are processed, they are usually georeferenced into a geographical information system (GIS), computer-aided design (CAD), or graphics package for further interpretation and inclusion in a survey report. Data are usually presented in a two-dimensional, georeferenced raster grayscale shade plot, and an archaeological interpretation is conducted using vector graphics in a layered system, allowing the geophysicist

to turn on or off the particular interpretation classes to highlight different aspects of the data. The visual range of the data is usually limited to a few nT either side of zero for final publication. However, this is dependent on the magnitude of the archaeological anomalies to be highlighted. In the UK, for example, ± 2 nT up to ± 10 nT may be fairly common display ranges for relatively “average” sites, where a reasonably strong magnetic contrast exists. In cases where the overburden to archaeology is large, or the magnetic contrast is particularly weak, this scale can be made even tighter, for example down to ± 1 nT, to try to accentuate the weak magnetic anomalies as much as possible. The choice of the display range is subjective, but should highlight the anomalies of archaeological interest, as well as all other anomalies of importance, as this can dramatically alter the ability to interpret and translate the data in an informed and complete way.

Other visualization techniques are sometimes incorporated to help aid interpretation, such as draping data over a digital elevation model (DEM), or lidar data to help to position subsurface anomalies within a real-world landscape. Magnetometer data may also not necessarily always be considered on their own, and complementary geophysical techniques will aid interpretation of the datasets. In the case of multiple surveys conducted over the same area, visualization techniques can be considered that combine the magnetic data with other geophysical techniques (Schmidt 2001; Kvamme 2006a). Such visualizations involve statistical manipulation of the data, and the use of color accentuates the various anomalies present in each dataset. Further visualization of the magnetic data may involve three-dimensional surface creation or modeling, although the latter is still generally rare in a common geophysical project.

Visualization of Soil Resistance Data

PAUL N. CHEETHAM
Bournemouth University, UK

Background and history

Resistivity survey instruments measure the ability of the ground to resist an electric current. In the past their analog output was visualized by plotting directly onto an x-y plotter, or readings were taken from a meter dial while hand-recording these values on paper. From these values, resistance profiles could be graphed (see Clark 1996 for examples of early resistance data visualizations), or, for a grid of readings, they could be manually contoured or used to create “dot-density” plans. In dot-density plots, each sampling unit—normally a 1 m grid—was manually “dotted” with randomly placed dots, the number of dots being proportional to the value of resistance. While field recording remained manual, mainframe and minicomputers, when available, were employed to automate contouring and dot-density visualizations of the resistance data. In the 1980s, analog meters were replaced by digital displays. Following this, digital data recording was introduced, in which an analog to digital converter allowed data to be stored, downloaded, and manipulated by computers. Digital data processing and the availability of high-resolution grayscale and color graphics have impacted on the visualization of resistivity data. Area resistance survey is variously termed *earth* or *soil resistance/resistivity*, or *geoelectrical* survey, while depth profile surveys are termed *pseudosections*, *geoelectrical* or *electrical imaging*, or *electrical* or *resistivity tomography*.

Area survey correction, processing, and visualization

Most commonly soil or earth resistance survey (ER) readings are taken on a regular grid, often at 1×1 m reading intervals for general prospecting, and are surveyed in survey grid units such as of 20×20 m, which gives 400 readings in each survey grid. Multiple survey grids are then combined to make the overall survey dataset *composite*. However, data collected with the twin electrode array, the most frequently employed array, have an inherent data-correction requirement, because the resistance reading is affected by the remote electrode positioning, requiring grids to be matched. This is accomplished by adding to one grid or subtracting from it a bias value, so as to make it match the adjacent grid; and this is done manually or by computer algorithm. Without correction, the survey grids would show and would visually and mathematically interfere with any analysis. Twin electrode data may need destriping and, where the immediate surface is very dry or stony, a despiking algorithm may be needed to remove extreme or spurious readings caused by poor electrical contact. Survey electrode arrays such as the Wenner or square arrays do not require grid matching or destriping. If surveys are conducted over an extended period of time, then there may be grid-matching issues that are not due to the array but result from overall changes in ground moisture conditions, which affect the range and contrast in the values. While range-matching algorithms help correct such differences, large surveys should be completed rapidly, by using multiple or mechanized instruments, or should be surveyed under the same ground moisture conditions.

After data correction there should be a clean set of resistance values that can be visualized. While early work used contouring and dot-density plots for visualizing the data (e.g., Clark 1996, figs. 2 and 110 respectively), grayscale plots are now

almost universally employed. In grayscale plots, white is more frequently used for low resistance and black for high resistance. Some reverse this scale, as human vision is more sensitive to changes at the light end of the grayscale than at the darker end of the range (Dennis 2004). In practice, the grayscale should be always reversed during analysis, to avoid this issue.

Visualizing the raw data as a grayscale plot with the range from the minimum (white) to the maximum (black) values and with linear intervals for the shades in between may produce the desired archaeological outcomes. In practice, it is likely that the data range will need to be clipped—that is, the minimum plotting value increased and the maximum decreased—often by being set at plus or minus a number of standard deviations, to bring out more visually low-resistance and high-resistance anomalies by increasing their contrast. The use of standard deviations is rather problematic, as resistance survey data do not normally produce a Gaussian distribution of values. If they do, then it is likely that the site is devoid of any archaeological or other anomalies of interest, and you are just measuring natural random variation in an otherwise uniform geology. That the distribution of resistance values is not normal is down to the physics and to the way the resistance is measured.

The difference between *resistance* and *resistivity* is that *resistivity* is the *specific resistance* of a material. Small Perspex resistivity “soil boxes” can be used to make measurements of resistivity. As the resistance recorded by the survey instrument is a measure of resistivity, and as it is changes that need to be mapped, converting all our resistance values to resistivity is not required. However, the resistance measured is a bulk value. For any resistivity array, a calculation of resistivity can be made; but, because of the unknown inhomogeneous nature of the subsurface, this can only be a “sum” of all the relevant contributing elements, and so it is termed an *apparent resistivity*. It is only required to calculate apparent resistivity when there is a need to compare or combine results from different arrays, or when creating depth profiles.

For a feature in ground of the same size, shape, and depth that is, equally, less resistive or more resistive than the background value, the more resistive feature will cause a greater

absolute resistance value change than the lower resistive feature. This means that earth resistance surveys show high resistivity features such as walls much more strongly in relation to background values than low resistivity features such as ditches, the latter being also inherently likely to be of lower resistivity contrast anyway. This further means that the resistance data distribution from a typical archaeological site is skewed, with the tail toward high resistance. This can result in poor visualizations, if simply an equal number of plus or minus standard deviations is used. To alleviate these issues, three approaches can be taken:

1. Manually selecting the clipping values by inspecting the histogram of the data. This allows visual emphasis on values that are beyond the clipping values and provides a more subtle view of variations within the mid-range of values, which are likely to be features within the background variation that can only be identified by pattern and morphology.
2. Using histogram equalization to spread out and allocate equal numbers of data points to each grayscale class, which in effect flattens the histogram. As in (a), this, without clipping, groups extreme values together, while further spreading the mid-range values to allow the detection of subtle anomalies that may exist within the noisy part of the distribution.
3. A nonlinear (e.g., logarithmic) scale which compresses the high resistance tail and has more class intervals at the low-resistance end of the distribution, so that subtle low-resistance contrast anomalies are brought out at the expense of the high-resistance part of the distribution. Such nonlinear scaling is frequently used in electrical imaging (see below).

Ideally, earth resistance data should be visualized without further processing. In practice, earth resistance data can benefit from applying mathematical filters either to enhance individual readings by removing wider background values (high-pass filtering) or to suppress individual readings so as to remove “noise” in the data and see larger features more clearly (low-pass

filtering). The latter can be used where the immediate surface has an extremely variable resistance, causing deeper, weaker anomalies to be drowned out by this “noise.” This is because resistance arrays are most sensitive at the surface, the sensitivity falling off rapidly with depth (Clark 1996, fig. 25). Such visually intrusive noise is caused by recent cultivation, extreme stoniness, or in dry conditions and a low-pass filter can remove it, but this will be at the expense of smaller anomalies of the dimensions of the reading interval.

While resistance arrays detect down to an infinite depth, most of the response will come from near the surface, where the archaeology is; but strong underlying geology may drown out subtler archaeological variations. A high-pass filter uses a “window” of values, for example 3×3 or 5×5 , to emphasize the central value and to remove the background.

Filtering needs to be done with a clear understanding of what is being lost and gained. In reports, it is a requirement that the unfiltered data be presented along with the processed data, to allow the user to visualize any gains and losses. Additionally, filtering alters the original values of resistance measured and, in the case of high-pass filtering, introduces negative resistances unless a bias is added, making numerical scales meaningless. The effect of applying both low-pass and high-pass filtering sequentially to the same dataset is illustrated in David, Linford, and Linford (2008, fig. 24), although it is debatable whether the final twofold filtered grayscale image enhances an interpretation provided by the raw data visualization. Other filtering methods can be applied to remove or reduce the visual effect of cultivation lines that may appear on surveys (Dennis 2004).

An alternative to the presentation of resistance data as a plan is to create a three-dimensional surface where the resistance value is used to create what is effectively resistance topography. This presentation is particularly useful for earth resistance data, as high-resistance peaks often relate to “positive” archaeological features such as walls, while low-resistance troughs often relate to “negative” archaeological features such as pits and ditches. These plots can be more visually appealing and understandable to nonexperts, but seasonal reversals of negative features and paradoxical responses may diverge from such models.

Electrical imaging

Where resistance data are collected at differing electrode separations along the same traverse, the resistivity can be calculated and plotted at notional depths below ground level. The value of the notional depth is related to the particular array and the electrode separation. For a twin electrode array, the factor is 0.867 the mobile electrode separation (see Loke 2016, table 2). Using these values it is possible to visualize the data as a sectional elevation through the subsurface. The raw resistivity data values can be presented as what is termed a *pseudosection*, or a mathematical inversion used to estimate the true values of resistivity in the subsurface, both as shown in David, Linford, and Linford (2008, fig. 25). Note that the visualization scale is in color and is nonlinear, and the depth scale is exaggerated. This is the most frequent mode of visualization for electrical imaging data, although grayscale visualizations are also used.

A number of such depth profiles are combined to create a three-dimensional block of data, then cutaway models or generating isosurfaces can be used to visualize the data within the block. The latter isolate volumes or data that are above, below, or between set threshold levels. This visualization of individual anomalies allows the user to investigate morphology and physical relationships. Three-dimensional visualizations are common across a range of archaeological data and for more general information the further reading sources should be consulted.

Data fusion and resistance data

The most challenging approach to visualizing earth resistance data is to combine these data with other geophysical or related datasets. Complex methods have been explored by researchers such as Watters (2006), but the most obvious one is to combine resistance data with topographical data by draping the former over the latter in a three-dimensional visualization. This is useful on sites with slight earthworks representing potential walls and ditches, which would correspond to high- and low-resistance anomalies; the two datasets visualized together

can enhance the interpretation of each, taken individually. In addition, extreme changes in topography can introduce false anomalies that could be interpreted as archaeological features and not simply as topographical effects in the data. Attempts have been made to combine resistance and magnetometry data, either mathematically or by draping the magnetic data over a wireframe representation of the resistance data. A visual approach is using color palettes (e.g., white–red for soil resistance and white–green for magnetometry) that, when overlaid and when the colors are mixed, allow the user to see where anomalies are only high-resistance (red), only positively magnetic (green), both (brown), and low or negative (white). Attempts to combine the earth resistance data with other datasets visually or mathematically are problematic because of the issue of assigning the relative weighting of different datasets to the final visualization.
